Thyroid-Stimulating Hormone of Anterior Pituitary Gland.—The experiments of Kippen and Loeb indicate that the greater the doses of extract of anterior pituitary given to guinea-pigs, the greater the changes produced in the size of the acinus cells, in the consistency and absorption of the colloid in the irregularities in the shape of the acini and, particularly, in the number and size of the papillas formed and in the number of slits which appear. The maximal changes reached a greater intensity in the animals injected with larger amounts of extract. These changes are more marked at an earlier date than in animals receiving smaller doses, and the period during which there is an increase in the effects of the extract has a greater duration and the maximum of the changes is therefore reached somewhat later in these guinea-pigs than in the ones receiving smaller doses. Further, a higher level of hypertrophy is maintained for a longer time and the gland returns to its normal condition later in these animals. The curves representing the mitotic proliferation differ in some respects from the curves representing the other signs of thyroid hyperactivity. Irrespective of the doses given, the proliferative activity reaches a maximum after two injections and then falls, in all instances, more steeply in the animals receiving smaller doses. The fall in mitotic proliferative activity takes place at an earlier date and is much more precipitate than is the case of the other structural changes indicative of hyperactivity of the thyroid, the curves representing the latter are flatter than those representing the proliferative activity. It is impossible to prevent the retrogressive changes or to diminish them by using smaller doses for injection. The smaller doses lead to a more rapid return to a normal state of the thyroid. The latter behaves as though there were a natural tendency for it to return to the normal state, and larger amounts of extract are necessary in order to delay this return. After smaller doses the return to the normal state is more rapid and more complete. As far as the number of mitoses is concerned, the decrease is not due to the production of antibodies, and even in regard to the other structural features it is very improbable that these are entirely due to such a factor, considering the negative results that were obtained several years ago. The studies show that it is possible, by means of two injections of 2 cc. of extract of anterior pituitary gland, to raise the proliferative index of the thyroid of the guinea-pig about a thousand times, namely, from an average of 150 mitoses to a maximum of about 190,000, within as short a time as two days.

Theory and Practice of Full Denture Construction H S Neal—p 67

Diagnosis of Ulcer and Carcinoma of Stomach.—The comparisons between gastric and duodenal ulcer and gastric cancer given by Howze entail the following. 1 Gastric ulcer ceases to grow after attaining a size of about 2.5 cm in diameter. 2 Duodenal ulcer is more easily diagnosed than gastric ulcer.

3 Bleeding duodenal ulcers are usually situated on the posterior wall of the first portion of the duodenum 4 Hunger pains are usually characteristic of duodenal ulcer 5 Hemorrhage is more frequent in duodenal than in gastric ulcer 6 Obstruction is more frequent in gastric than in duodenal ulcer 7 Hour-glass contraction occurs in about 7 per cent of gastric ulcers 8 Cancer develops on gastric ulcer in about 10 per cent of all cases 9 The most frequent type of cancer found in the stomach is adenocarcinoma 10 Gastric symptoms are not infrequent in the early forms of cancer There is a familial tendency to develop peptic ulcer Pain is the chief symptom found in peptic ulcer, vomiting, loss of weight and appetite in cancer The history of symptoms in peptic ulcer is usually less than one year before hospital admission, in cancer the symptoms have been present for two years or more. Nearly all cases of ulcer give a history of attacks with remissions, the majority of cancer cases give a history of more or less constant distress The pain in cases of ulcer is usually described as being in the epigastrium cramplike, burning or gnawing in type, whereas cancer patients usually describe their symptoms as being a dull, vague or heavy feeling associated with a sense of fulness The symptoms in the ulcer group come on much earlier after meals than those of the cancer group Relief of pain by alkalis or food is characteristic of the ulcer group, vomiting or belching are the common methods of relief in cancer cases The roentgenogram is the chief means of diagnosis and differential diagnosis of the three types of lesions

*Intravenous Manganese in Treatment of Psoriasis Preliminary Report of Successful Cases J Barr Paterson—p 376

Continuing Program of the Medical Society of New Jersey L A Wilkes Trenton—p 380

Intravenous Manganese in Treatment of Psoriasis—Barr has used a preparation of manganese that may be given intravenously without ill effects This preparation contains a combination of manganese chloride 0.029 Gm and calcium chloride 0.0095 Gm in 5 cc. of physiologic solution of sodium chloride The author has given 100 intravenous injections of manganese without any serious reaction The only systemic reactions noted were a slight rise in pulse rate, about 10 per minute, a mild suffusion of the face, and in some cases a slight

lightheadedness, all of which passed off in a few seconds. These reactions are not limited to manganese but may result from any colloidal preparation given intravenously In no case was there any rise in temperature, vomiting, or any sign of toxicity following the injections In several cases, when improvement was not rapid enough, a decrease of the dosage and an increase of the interval between injections gave rise to a more marked improvement Seven cases are reported, five of which showed complete improvement and two partial improvement Particularly advantageous for therapy with manganese are the highly dispersive colloidal manganese compounds The minute quantity of manganese present combined with calcium chloride makes manganese chloride an ideal preparation for the intravenous treatment of psoriasis Its freedom from toxicity and ease of administration and the rapidity of disappearance of the lesions without any local therapy make manganese chloride the preparation of choice in the treatment of psoriasis While this series is small, the results obtained are so satisfactory that continuation of this method of treatment appears justifiable

*Irritants in Adhesive Plaster L Schwartz and S M Peck—p 811

Irritants in Adhesive Plaster—Schwartz and Peck tested twenty-one subjects showing various degrees of adhesive plaster reaction with eleven ingredients of adhesive plaster One of these developed a generalized reaction so that individual tests could not be evaluated Seven of the remaining twenty were negative to the patch tests Of the thirteen remaining, eight showed positive reactions to wood rosin extracted from the stumps of pine trees eight to so called Burgundy pitch, six to I-rosin five to South American Para rubber, which had been milled washed and dried two to beeswax two to olibanum, and one each to hydrous wool fat, orris root and gutta serena. All the subjects who showed marked reactions at the first removal of the adhesive tape with continued intensification at the second inspection showed positive reactions to one or more of the rosins and 50 per cent were sensitive to rubber Seven of the subjects tested who showed a negative or only a slight erythema at the first inspection but who later developed delayed reactions were sensitive to one or more of the rosins, and two were sensitive to rubber The tests seemed to indicate that there are two types of reactions to adhesive tape one is purely chemical and due to resultant maceration and mechanical trauma from the application and the removal of the plaster and the other is due to hypersensitivity to one or more of the ingredients of the plaster The results indicate that the chief irritants in the adhesive plasters that were tested are the rosins,

in which can be included the so called Burgundy pitch and the smoke-cured wild rubber, of which South American Para is an example. An attempt was made to determine whether complexions or previous diseases of the skin or an allergic diathesis had a predisposing effect on sensitivity to adhesive plaster. All the subjects patch tested with adhesive plaster were questioned as to these facts. No such correlation could be established.

Muscular Activity of Stomach and Abdominal Distress—Welch shows that on the first taste of food the musculature of the stomach normally relaxes. This is a taste reflex and not a gastric reflex. In the presence of intragastric or extragastric visceral disease, either abdominal or pelvic, there is frequently associated a distortion of this normal reflex, consisting usually of marked changes in the muscular tonicity of the stomach with or without increase in gastric peristalsis. This inversion of the normal feeding reflex is usually associated with so-called symptoms of indigestion and dyspepsia centering round the epigastrium. The degree of distortion of the normal feeding reflex apparently is not influenced by the character of gastric secretion. Manifestly, the clinical problem presented by this type of case is the discovery of the source of irritation which is causing distortion of the normal taste reflex. Certainly, these perhaps inadequate glimpses at the actual changes in the muscular activity of the stomach associated with varying types of disease have greatly simplified the diagnostic and the therapeutic problem connected with that large group of gastro-enterologic patients complaining of dyspepsia.

The Relief of Pelvic Pain P G Flothow Seattle—p 207

Recognizing the Patient Who Will Probably Not Be Helped by Abdominal Operations—Alvarez points out that the diagnosis of functional disease should not be made mainly by exclusion but mainly on the basis of a careful history and on the recognition of a well known syndrome. Experience indicates that many 'emergency' operations should have been deferred until a careful study was made of the patient. A large proportion of interval appendectomies should have been 'explorations'. It is an exploration of the abdomen that the patient needs whenever the abdomen is opened and the diagnosis is not clear. It is not advisable to operate on persons with conditions of doubtful pathogenicity such as ptosis or on persons who are psychopathic, hypersensitive, constitutionally inadequate, highly allergic or migrainous or on persons who are on the verge of a nervous breakdown. It is often unwise even to explore the abdomen of a person with a severe crisis-like type of pain that is not related in its comings and goings to any function of the digestive, urinary or genital tract. It is usually unwise to operate on persons who have already been operated on several times without success. The author describes three syndromes of pseudo-ulcer, pseudocholecystitis and pseudo-

appendicitis that are seldom cured by operation. Judging by the results obtained, it is rarely advisable to operate for adhesions.

Pelvic Pain—Flothow is of the opinion that the majority of cases of pelvic pain that do not respond to ordinary gynecologic treatment may be relieved by interruption of the afferent pain fibers coursing through the superior hypogastric plexus. This interruption of afferent fibers may be accomplished by surgical removal or by alcohol injection of the plexus. Cases of functional dysmenorrhea having no associated pelvic disease are particularly adapted to treatment by alcohol injection. Diagnostic injection of the pelvic sympathetic nerves should always precede any surgical procedure directed toward the relief of pain by denervation of the superior hypogastric plexus. If properly selected by means of diagnostic injections, and those in which the pain is of psychogenic origin are excluded, practically all cases of pelvic pain can be relieved by one of the two methods.

Cervical Ribs—Robinson and his associates list the two indications for surgery in cervical ribs (1) interference with blood flow through the subclavian artery and (2) interference with the brachial plexus manifested by pain, paresthesias, tingling, numbness, sensory changes and so on. Operation should be avoided when the symptomatology is mild and when there is an underlying neurotic tendency, especially if the symptoms depend only on irritation of the brachial plexus. The surgical procedure in dealing with cervical ribs for the most part has been complete removal of the rib. Adson found that, in cases in which the subclavian artery and at times a trunk of the plexus was caught between the anterior end of a rib and the lateral border of the anterior scalenus muscle, section of the muscle at its insertion resulted in relief of symptoms. A case of this type is presented in which section of the scalenus muscle released the subclavian artery from pressure and gave complete relief. It is the authors' belief that in similar cases when the symptomatology can be definitely traced to disturbed blood flow and when involvement of the plexus cannot be demonstrated at operation, this procedure is entirely adequate. However, in those cases in which interference with the brachial plexus can be demonstrated both before and at operation they believe that excision of the rib in most cases remains the operation of choice. A midclavicular incision can be extended anteriorly to the border of the sternocleidomastoid muscle or posteriorly to the trapezius and is then adequate for either procedure.

Relapsing Febrile Nodular Nonsuppurative Panniculitis—Weber suggests that iodides (or bromides?) may, in certain rare, idiosyncratic persons, give rise to a syndrome resembling "relapsing febrile nodular nonsuppurative panniculitis," and that in one or two of the nodules the panniculitis may proceed to suppuration, it seems, therefore, that the nodules represent local phlegmonous areas—tense with inflammatory edema—which may actually suppurate. He does not mean that cases of relapsing febrile nodular panniculitis are necessarily due to either of these drugs

Tribrom-Ethanol as Complete Anesthetic in Children—Boyd used tribrom ethanol in the production of complete surgical anesthesia in 700 children from the age of 3 months to 13 years. He found that tribrom ethanol can be given to children as a complete anesthetic with safety, provided a careful watch is kept for danger signals and the patient is treated accordingly. Complete tribrom-ethanol anesthesia in children is better and more suitable than basal anesthesia followed by an inhalation anesthetic. Complete tribrom-ethanol anesthesia in children approaches more nearly the ideal anesthetic. It is much safer in children than in adults, as in the former there is better detoxication and elimination. The best method of administration to produce complete anesthesia is to combine 0.175 Gm. of tribrom-ethanol per kilogram of body weight with morphine and atropine according to age, and from 20 to 30 cc. of procaine hydrochloride as a field block. A 3 per cent solution of tribrom-ethanol is better retained than a 2.5 per cent solution. The depth of anesthesia is best assessed by nipping the skin of the neck and watching the arm for movements. The fall in blood pressure is not of serious moment. Complete tribrom-ethanol anesthesia is contraindicated in extremely young and cachectic children.

*Pernicious Anemia Some Considerations in Regard to Its Nature and Pathogenesis. J P McGowan —p 293

Alexander Hughes Bennett and the First Recorded Case in Which an Intracranial Tumor was Removed by Operation E Bramwell —p 312

Pernicious Anemia—McGowan divides large red blood cell anemias into the megalocytic and the macrocytic. The appearance of the former depends essentially on organic changes

in the bone marrow and is associated with a return to the early embryo form of erythropoiesis, in the latter the bone marrow is healthy and the phenomena in the blood and the general condition are brought about by a deficiency of the antianemic factor, whether due to an absence of intrinsic or extrinsic factor, nonabsorption of the product of their interaction or failure of the liver to elaborate this to the fully formed liver agent. Erythropoiesis as it occurs in the healthy marrow is discussed, and this is followed by a consideration of the process as it takes place in pernicious anemia. The bearing of constitutional predisposition or diathesis together with the factors implicated in the onset of subacute combined degeneration is also discussed, while evidence is adduced to show that pernicious anemia, once it is firmly established, is never recovered from, in the sense that the bone marrow never again returns to normal.

Tuberculin Reactions of the Hongkong Chinese with Especial Reference to Use of Tuberculinoprotein L. J. Davis and J. S. Guzdar —p 300

Change in Virulence of Strain of Trypanosoma Brucei—Browning and Gulbransen perceived that a strain of Trypanosoma brucei, when recently introduced into mice and imperfectly accommodated to this species of host, produced infections relatively resistant to various trypanocidal drugs. When the strain had become highly accommodated and its pathogenicity increased to a maximum as the result of repeated passages, infected animals were readily cured. The mechanism on which this difference in resistance may depend has not been investigated. However, the drugs acted poorly when the strain was in an attenuated state, as shown by the prolonged course of infection and the occurrence of marked fluctuations in the number of parasites present in the blood. Thus the chemotherapeutic response was weak at the time when the host itself was able to exercise an effective resistance. Later, when the host's resistance had become negligible, the curative action of the drugs was pronounced.

Foot Perspiration—Colin-Russ states that perspiration of the human foot is essentially an organic dispersion in sodium chloride solution. Judging from its effects on footwear, it is fairly active chemically and physically. The physical action would be more noticeable in the case of profuse perspiration from a healthy subject, while the chemical character would be markedly evident in abnormal perspiration arising from a pathologic cause. In an average manner, normal perspiration functions chiefly as an aqueous solvent with hydroxy acid characteristics of an initially small extent. In the cumulative action of perspiration the total solids of the emulsion bear

some significance. The clothing of the foot may be of unsuitable material, e. g., as an extreme case patent leather for advanced gouty subjects, or the solvent or chemical interaction with external agents may aggravate trouble following on mere absorption alone through the skin, e. g., aniline or nitrobenzene from wrong shoe dyes has been known frequently, in Holland, France and America, to cause toxic symptoms, through successive solubilization by perspiration. Further work is desirable to establish the presence of enzymes. Failure so far to detect them may probably be the result of limitations of method and conditions.

Carriers and Return Cases in Scarlet Fever—In view of the high carrier rate on discharge from the hospital, Brown and Allison believe that the bacteriologic examination of swabs from scarlet fever patients is of no value in the detection of probable infecting cases. There is a definite relation between the degree of infection, as measured by the profusion of hemolytic streptococci in cultures on discharge, and the likelihood of the patient infecting others. The causal connection between the "infecting" case and the return case is strongly supported by finding the same serologic type of *Streptococcus pyogenes* in the two. A patient who has had complications in the hospital is slightly more liable to become an infecting case than one whose course has been uncomplicated. The age group in infecting cases is from 5 to 10 years. The majority (70 per cent) of the return cases occurred within fourteen days of the arrival home of the infecting case. Overcrowding in the home and the number of the susceptible persons exposed do not appear to be important factors in the production of return cases. A history of tonsillectomy does not appear to bear any important relationship to the occurrence of infecting cases, but the desirability of further investigation of this question and the relation of the condition of the tonsils to their infectivity is indicated. Discharge from the hospital as early as is consistent with a satisfactory clinical condition is shown to be advantageous from the point of view both of the patient and of the hospital administration. The administration of scarlatinal antitoxin is likely to render a patient less liable to convey infection on discharge.

38: 133-144 (June 1) 1935

*Leprosy. Report of Twenty Seven Cases Treated with Anthrax Vaccine J. N. Roussel—p. 133
Definition of Renal Glycosuria S. Vatcher and M. Douglas—p. 137

Leprosy Treated with Anthrax Vaccine—Roussel used anthrax vaccine in the treatment of leprosy, giving more than 700 injections without having had any bad results. He used 0.125 cc. as the initial dose. The doses were spaced five days apart, and the quantity was doubled each time until a dose of 2.5 cc. was reached. A total of 30 cc. was given. It required about ninety days in which to give it. In the average case there is a slight elevation of temperature in the evening of the day of the injection. It rarely reaches 100 F. Only after the vaccine has been stopped for two or three months does anything of interest happen, and this usually manifests itself in two ways. In about two thirds of the cases the lesions gradually fade away, the anesthesia being last to disappear. In the others a multiform erythema develops sometimes of the bulbous type but more often of the nodular type, which is not distinguishable from an ordinary case of erythema nodosum. There are more lesions on the extremities, and the leprosy lesions become much inflamed and painful—so much so that one patient described them as being more painful than a boil or a corn. The temperature range is high (from 103 to 104 F. for about three weeks). Antipyretics seem to have little effect on the temperature, and analgesics seem not to relieve the pain. When the fever subsides the nodules disappear, and in the course of a comparatively short time the lesions of leprosy also disappear together with the anesthesia which latter however takes place more slowly. On careful investigation the author finds that there has been no spread of the disease in the families of those whom he has treated. Of twenty-seven cases in which he is able to say with any degree of certainty what happened to them seventeen were of the maculo-anesthetic,

nine of the tubercular and one of the mixed type. Of the patients with the maculo-anesthetic type, fifteen are apparently well. The patient with the mixed type is apparently well, but the nine patients with the tubercular type have not been benefited. Acid-fast bacilli were found in six of the maculo-anesthetic cases, the nine tubercular cases and the one mixed case. Two of the patients with the maculo-anesthetic type are still under observation. They have made remarkable progress.

Abdominal and Circulatory Phenomena of Allergy—Ryle defines certain abdominal syndromes and circulatory disturbances that may be reasonably regarded as expressions of the allergic state and, on a purely clinical basis, suggests criteria without which one should be unwilling to accept them as genuinely allergic. He believes that no abdominal or circulatory disturbance should be labeled "allergic" unless two or preferably more of the following postulates are fulfilled. 1 The symptoms should bear close comparison with those observed in human anaphylaxis or serum sickness. 2 There should be a history of idiosyncrasy to some food, beverage, tobacco, drug or other extraneous substance. 3 There should be either in conjunction or alternating with the abdominal or circulatory episodes other accepted allergic phenomena, such as asthma, hay fever, urticaria or angioneurotic edema. 4 There should be a family history of these disorders. 5 The disturbances should show some such intermittence or periodicity as obtains with other allergic disorders. 6 Every care should have been taken to exclude organic disease. There is little to distinguish the circulatory phenomena and subjective sensations of some vasovagal attacks (Gower's syndrome) from those of anaphylactic shock, and cases of Gower's syndrome may create, at the time of the attack, an equivalent degree of alarm. A case of Gower's syndrome following a second inoculation of tetanus antitoxin is described.

Volkmann's Paralysis—Sorrel describes a method of treating Volkmann's paralysis by means of shortening the antibrachial skeleton. He makes an osteotomy in chevron form of the two bones of the forearm using an electrical saw. The shortening is made sufficient to allow complete extension of the fingers. At a previous or subsequent operation the arterial bifurcation is explored and in cases in which the arterial segment is definitely altered resection is practiced.

 *Serotherapy of Gangrenous Appendicitis and Peritonitis M Weinberg and M Laquière—p 877

Serotherapy in Appendicitis and Peritonitis—Weinberg and Laquière discuss the use of serums active against the dominant microbes of gangrenous appendicitis and peritonitis. For the last three years they have used a mixture of their antgangrenous serum and an anticolon bacillus serum and a complementary one. The latter is designed to combat the secondary microbes, aerobic and anaerobic which are generally slightly pathogenic but which in certain cases play an important part in the evolution of grave appendicitis. These are the enterococci streptococci Bacillus ramosus Staphylococcus parvulus Bacillus fusiformis B funduliformis and so on. Forty patients have been treated by this mixture with one fatality. From 60 to 80 cc has been injected intraperitoneally and an equal amount intramuscularly before the end of the operation. In the majority of cases the disease is relieved the day after the operation. When this method is employed by others the authors advise that the mixture be used only in the presence of grave complications of appendicitis viz toxemia or peritonitis. The mixture should consist of 30 cc of polyvalent antgangrenous serum 40 cc of anticolon bacillus serum and 10 cc of complementary serum. Equal amounts should be injected intraperitoneally and intramuscularly. If the patient is in an especially serious condition the injection should be intravenous. To avoid anaphylactic phenomena the injection should be made at the end of the operation while the patient is still under the influence of narcosis. The authors believe that treatment with this mixture should form an obligatory part of the surgeon's therapeutic arsenal.

 *Transformation of Osteogenic Disease into Chondrosarcoma Robert Didier—p 915

Transformation of Osteogenic Disease into Chondrosarcoma—Robert-Dider reports a case of transformation of a thoracic exostosis into a chondrosarcoma in a woman aged 31, who had a massive exostosis of the anterior thoracic wall which had grown extensively for three months. Roentgen examination revealed an osseous tumor at the lower chondrocostal border of the left anterior side and the lower portion of the sternum. The roentgenogram had a characteristic nonhomogeneous appearance alternately clear and opaque and of irregular contours which is the usual one observed in chondrosarcomas. The tumor was excised. Histologic examination showed a chondro osteosarcoma with marked predominance of cartilage formation. The zones showing malignant changes were rare but entirely characteristic where they were encountered. There was a later recurrence and the tumor was removed again. Histologic examination at this time showed a fibrochondrosarcoma with polymorphous cells. The author concludes that early surgical ablation of exostoses is to be advised in order to avoid possible transformation into a malignant tumor.

 Roentgen Treatment of Polyneuritis Following Arspenamine Treatment of Posttraumatic Intracranial Abscess Compressing Cerebellum Emptying by Perforating Aspirating Needle Case G Egidi—p 1192

Liver Therapy in Polyneuritis—Corelli reports the case of a syphilitic woman, aged 23, who developed diffuse polyneuritis with motor paralysis after receiving arspenamine amounting to 315 Gm. Further injections of arspenamine caused an aggravation of the symptoms. The liberal administration of liver after the discontinuance of arspenamine resulted in the cure of the patient within six weeks. She was given 200 Gm by mouth daily and large doses of liver extract parenterally. As a complementary treatment the patient was given strychnine sodium salicylate and sodium iodide in daily doses of 0.003 Gm 3 Gm and 4 Gm respectively. The author advises the liberal administration of liver in early treatment of herpes zoster polyneuritis radiculitis myelitis and encephalitis following the arspenamine treatment of syphilis. He proved in his experiments that liver extracts have antitoxic properties. Of two lots of rabbits intoxicated with arspenamine those in the first lot which were given injections of liver extract, recovered sooner than the controls and those in the second lot, which received liver extract simultaneously with arspenamine, were able to stand larger doses of arspenamine (even larger than the fatal doses) than the controls. He also obtained satisfactory results from injections of liver extract in a clinical case of agranulocytosis and one of dermatitis, following the treatment with arspenamine. He believes that an early and intense liver treatment is indicated in the pathologic conditions that complicate the gold treatment as well as in toxic polyneuritis (lead and alcohol polyneuritis) and in the general toxic symptoms of the complications. His belief, although not as verified is based on the clinical and probably pathogenic analogy that exists between the complications of arspenamine treatment and those of other forms of chemotherapy especially those of gold treatment. The liver treatment acts by an antitoxic mechanism in these complications.

Gastroduodenal Ulcer and Biliary Lithiasis—Robbians and Tanturi advise that a careful gastroduodenobiliary examination be made during cholecystectomy in order to determine whether there is a coexisting gastroduodenal ulcer with biliary lithiasis. They found this to be the case in twelve of 1,400 patients on whom the operation was performed. The authors believe that there is a pathogenic relation between biliary lithiasis and the type of gastroduodenal ulcer described by Judd as ulcerogenic duodenitis. The pathogenic mechanism of ulcers of this type is as follows. The modifications in the nature and mechanism of regulation of the bile in biliary lithiasis produces duodenitis in which pyloric spasm originates. The lack or insufficiency of the physiologic duodenal reflux impeded by the pyloric spasm disturbs the acid-base balance of the gastric secretion. The gastroduodenal reflux impeded by the sensitivity to the action of the gastric secretions and not being protected by alkaline secretions is acted on by the gastric secretions resulting in the formation of ulcers. The pathogenic theory of the authors is based on the results of experimental gastroduodenal ulcer after derivation of the bile in which the presence of duodenitis was constant, and also on the results of Judd's histologic studies of ulcerogenic duodenitis which seem to be superimposed on those obtained in experimental gastroduodenal ulcer by derivation of the bile.

- Masked Fractures of Neck of Femur V. Aalkjaer —p 548
- *Experimental Studies on Relations Between Vitamins and Healing of Wounds H. J. Lauber —p 565

Disturbances in Secretions of Pancreas—Jorns names three tests that have gained importance in the diagnosis of acute disorders of the pancreas (1) the dextrose tolerance test, (2) the determination of the diastase content of the blood and urine and (3) the demonstration of atoxyl-resistant lipase. Then he gives his attention to disturbances in the internal and external secretion of the pancreas in injuries of that organ, describing the injuries caused by a blunt force. He discusses isolated subcutaneous transverse rupture of the pancreas, posttraumatic necrosis of the pancreas, pancreatitis and the lesions resulting from contusions of the pancreas. He thinks that every injury of the pancreas leads to a temporary functional impairment of the organ. It has been proved by experimental and clinical observations that such functional disturbances not only develop in cases in which ruptures of the organ result but are even more pronounced in cases of crushing and contusion. A stasis of short duration and circulatory disturbances in the organ may produce a temporary impairment of the islands and hyperglycemia. Aberration of the diastase may be produced by passive congestion of the secretion within a few lobes of the gland. Lipase is liberated and resorbed if glandular cells are destroyed. The determination of the lipase is considered one of the most sensitive tests. The author emphasizes that, if in case of a trauma produced by the action of a blunt force on the upper part of the abdomen one or all three of the aforementioned functional tests are positive, the pancreas is involved, but the tests do not indicate the extent of the involvement. The advisability of an operation cannot be determined on the basis of an existing hyperglycemia or an aberration of the ferments. However, if a surgical intervention is done in case of demonstrated functional disorders of the pancreas, the organ should receive especial attention during the operation. The author thinks that an involvement of the pancreas alone or together with other organs is more frequent in case of blunt injuries of the abdomen than is commonly assumed or detected in the course of the clinical examination. However, injuries of the pancreas exclude by no means the existence of injuries of the spleen, the liver or other organs. Moreover, although the positive outcome of the functional tests indicates the involvement of the pancreas the negative outcome does not exclude the possibility of an impairment. But, although the diagnostic value of the functional tests is limited in injuries of the pancreas, they may be of great help in the further course of abdominal injuries produced by a blunt force, in that they indicate the retrogression of the organic changes. Moreover, the development of a posttraumatic pancreatitis will be more readily recognized with their aid.

Relations Between Vitamins and Healing of Wounds

—Lauber observed in animal experiments that the local application of vitamin A as a rule produces no acceleration in the process of wound healing. In the case of concentrated application of the vitamin he even noticed a slight retardation in the process of wound healing. Vitamin B₁ and vitamin C produce a slight retardation in wound healing when given in comparatively large doses. Vitamin D produces a slight acceleration of the healing process when administered in a low concentration when it is given in moderate doses vitamin D has no effect on the healing of wounds and when given in concentrated doses it even retards the healing process. The acceleration of the healing process is, however never as convincing as following the oral administration of small doses of vitamin A. The oral administration of vitamin D has no effect whatever on the wound healing process. The author evaluates the use of vitamin ointments in the treatment of wounds. He deprecates the lack of definite statements regarding their vitamin content and

considers inadvisable the use of ointments with numerous components, because it is never certain whether the one or the other of the various components may not be harmful for the wound. He stresses the importance of determining the cause of a poor healing tendency of a wound and shows that the treatment must be adapted to this cause. For instance, if diabetes mellitus or another metabolic disorder exists, it is necessary to treat this condition. If, on the other hand, a vitamin deficiency exists, the administration of vitamins will doubtless be helpful.

Therapeutic Action of Methylene Blue in Dyspnea Resulting from Pulmonary Processes—Schlunghaus, after pointing out that Ehrlich used methylene blue in 1885 for studies on the oxygen requirements of the organism, and that a number of American authors in recent years obtained favorable results with methylene blue in carbon monoxide and cyanide poisoning, reports that he used intravenous injections of 10 cc of a 1 per cent solution of methylene blue (methylthionine chloride) in conditions in which there was oxygen deficiency, particularly pneumonia. He administered the substance during the stage of severe cyanosis and dyspnea. The injection was made slowly. Shortly after the injection, or during it, a considerable improvement became noticeable. The cyanosis was lessened, the respiration was improved and the patients stated that they felt better. The author employed this treatment in fifteen cases, some of which he describes in detail. The action of one injection generally lasted for about twenty-four hours. After that, an increase in the cyanosis made another injection necessary. In some of the patients, however, a single injection was sufficient to tide them over the critical period. In one patient, with severe bronchopneumonia, the treatment failed and in several others the improvement did not immediately follow the administration of the methylthionine chloride and therefore cannot be definitely ascribed to it. The author concedes that its mode of action is not fully understood as yet, but he thinks that, even though it may not influence the disease process as such, it will serve its purpose if it frees the patient from an extremely painful condition.

Treatment with Hematoporphyrin.—Hühnerfeld states that his first therapeutic experiments with hematoporphyrin were based on the assumption that, because of its photodynamic properties, it might influence the sympathetic centers by way of the sensitization of the skin and perhaps exert a favorable influence on the melancholic and the endogenous depressive syndromes. These expectations were realized to a considerable extent. The author's clinical observations indicate that small doses of hematoporphyrin exert a favorable influence on the melancholic and endogenous depressive syndromes without causing undesirable secondary effects. He cites reports from the literature which indicate that his favorable results with hematoporphyrin have been investigated by a number of workers, among them Italian, American and French authors, who corroborate his observation that hematoporphyrin produces excellent results, and the majority agree with him that the treatment is superior to the treatments ordinarily employed in melancholia and depression. The treatment proved ineffective in only about 20 per cent of the cases. The author recommends the intramuscular administration of hematoporphyrin for the severest cases and oral medication for the others. The hematoporphyrin treatment makes it possible to restrict during the day the administration of morphine and barbituric acid preparations even in the severest cases, in cases of moderate severity, these sedatives may become entirely unnecessary.

Experiences with Cod Liver Oil Ointment.—Lücke employed cod liver oil ointment in numerous cases of paronychia, furuncle, carbuncle, abscesses and infected wounds and found

the treatment highly effective. He cites several cases, such as a second degree burn of the entire forearm, a trophic ulcer and an old fistula, in which the favorable effect of the cod liver oil ointment was especially noticeable. As a rule, the bandages were changed after forty-eight hours. This proved necessary especially in the suppurating processes. The author recommends cod liver oil ointment for the minor surgery that is done by the general practitioner.

Efficacy of Insulin—Meythaler and Schroff examined the efficacy of insulin in persons without metabolic disturbances and in patients having hepatic disturbances, pernicious anemia, cachexia of unknown origin, acromegaly, Cushing's disease and Addison's disease. They administered 1 unit of insulin per kilogram of body weight. In the patients with normal metabolism, the action was constant with regard to duration and intensity. The blood sugar content approached hypoglycemic values, but there were no symptoms of hypoglycemia. The insulin action subsided again in from sixty to ninety minutes. The action of the insulin in the patients differed greatly from that in normal persons. In patients with hepatic disturbances the blood sugar reducing action of the insulin is much greater than in normal persons and the return to normal blood sugar values is extremely slow. The intensity of the insulin action depends on the severity of the hepatic disturbance. The insulin action was strongest in parenchymal impairments of the liver. In pernicious anemia the insulin action was likewise prolonged and intensified. In acromegaly the action of insulin proved subnormal, the blood sugar returning to normal a short time after the injection. The action of insulin was extremely intense in a patient with the symptoms of Simmonds' cachexia. In Cushing's disease and in Addison's disease the insulin action was likewise far above the normal. In evaluating their observations, the authors point out that the injection of insulin produces a disturbance in the carbohydrate metabolism, the duration and intensity of which indicate the efficacy of insulin action. To overcome this disturbance it is necessary that all organs which exert a regulatory influence on the sugar metabolism function normally. The authors differentiate between organs, such as the hypophysis, the pancreas and the adrenals, which exert a superordinated regulatory action on the carbohydrate metabolism, and the organ in which the regulatory and counterregulatory processes take place, the liver. Their studies revealed that disturbances in both types of organs produce changes in the intensity of insulin action.

Vitamin C in Treatment of Gynecologic Hemorrhages—Junghans points out that the parenteral administration of vitamin C (cevitamic acid) arrests capillary hemorrhages. It has been observed that the intravenous injection of cevitamic acid checks the hemorrhages in hemorrhagic diathesis and in hemophilia as well as the suffusions in scurvy. The fact that cevitamic acid arrests hemorrhages of various origins induced the author to try it in gynecologic hemorrhages. The women were given in the morning and in the evening an intravenous or an intramuscular injection of 50 mg of cevitamic acid. The author treated a total of thirty-five women, the majority of whom had menopausal metrorrhagia. In thirty-three of these women the hemorrhages ceased on the fourth or, at the latest, on the sixth day of treatment. In two patients the cevitamic acid injections remained ineffective. The mode of action of the cevitamic acid is still unknown, but the author believes that a vascular action is the chief factor. He emphasizes the harmlessness of the cevitamic acid.

*Problem of Enucleation of Myomas During Gestation F Rhemann—p 298

Estimation of Number of Uterine Contractions—Presser calls attention to Frey's suggestion, according to which the counting of the uterine contractions is of vital importance for the prognosis of the delivery. Frey gives his attention chiefly to the total number of uterine contractions and not to the strength of the individual contractions. He has computed so-called highest numbers of labor pains for the various stages of the process of parturition, and he thinks that, after these highest numbers have been exceeded, the spontaneous delivery of a living child can no longer be expected. Frey also puts great stress on the importance of the time of rupture of the bag of waters. The author decided to reexamine Frey's results. He made careful observations on 400 parturient women, 100 primiparas and 100 multiparas without premature rupture of the bag of waters and on 100 primiparas and 100 multiparas with premature rupture of the bag of waters. The pelvic measurements were normal in all these women. The author found that the highest numbers of uterine contraction were exceeded thirty-six times. During the period of dilatation the highest number was exceeded fourteen times without a necessity arising of terminating the delivery by an operative intervention. Moreover, the author's expectant attitude did not result in the death of any infant, and the mothers likewise sustained no injury. Forceps delivery was resorted to in only six of the remaining twenty-two cases in which the highest number of uterine contractions was exceeded. If Frey's rule regarding the highest number of uterine contractions had been followed, forceps delivery would have been resorted to unnecessarily in thirty cases. The author concludes that the counting of labor pains is not more reliable as an indicator for the prognosis of delivery than is the duration of the process of parturition, the latter factor being also of some significance for the outcome. He considers it unjustified to make the number of uterine contractions the only basis of the prognosis and to disregard the duration and the frequency of the labor pains. He considers Frey's results a numerical corroboration of the well known fact that a long duration of the delivery makes the prospects for the child more unfavorable. He rejects the possibility of a definite rule that applies to every case of delivery.

Finger Prints of Twins—Following a brief review of the history of dactyloscopy, Bak reports the results of his studies on sixty-two pairs of twins. He observed certain similarities but never complete identity between the finger prints of twins. The similarity was greatest and most frequent in uniovular and equisexual twins. The similarity was less marked and applied to a smaller number of fingers in the binovular equisexual twins and still less in the binovular twins of opposite sexes. The author emphasizes that differentiation of the dactylograms is always possible in the binovular as well as in the uniovular twins.

Influence of Anesthesia and of Operation on Leukocytes—Eufinger and Kiltz found that ether inhalation anesthesia always produces a leukocytosis, which reaches its maximum from three to four hours after the anesthesia and completely disappears within twenty-four hours. If an aseptic operation is performed under ether anesthesia there likewise follows a leukocytosis, which reaches its maximum in from three to four hours and subsides after five days. Ether inhalation narcosis does not influence the adhesiveness of the leukocytes. The adhesiveness fails to change in spite of the leukocytosis. An operation is usually followed by a reduction in the adhesiveness, increasing and reaching its maximal value on the third or fourth day after the operation. This greater functional activity of the leukocytes is thus at its height at

the time when the preceding leukocytosis has just subsided. Beginning with the fifth day the functional increase subsides again, and it reaches its initial value on the ninth or tenth day. The occurrence of the maximal adhesiveness of the leukocytes at a time when postoperative thromboses are most frequent indicates a causal connection between the two phenomena. The change in the adhesiveness seems to be of greater diagnostic significance than the number of leukocytes.

Enucleation of Myomas During Gestation.—Rbemann points out that the advisability of an intervention in case a pregnancy is complicated by a myoma is still in dispute. Some recommend interruption of the pregnancy, others advise enucleation of the myoma with preservation of the pregnancy and still others await the delivery and after that consider an intervention. The author reaches the conclusion that the small, chiefly subserous myoma nodules, which cause no trouble, do not require an intervention during or outside of pregnancy. However, in case of a larger unfavorably located myoma that produces symptoms, enucleation is advisable during pregnancy, particularly in younger women, who should not be exposed to the eventuality of an extensive, sterility producing operation during pregnancy, delivery or the puerperium under much less favorable conditions. Enucleation during pregnancy is better for these patients even if the enucleation is followed by an abortion, but it may be hoped that the pregnancy continues or that the woman may become pregnant again and carry the pregnancy to term. The author thinks that particularly in the case of cervical, subperitoneal myomas the protrusion during delivery should not be left to accident, since these especially threaten the further course of the pregnancy and often necessitate later the removal of the uterus. In case of necrosis and infection of the tumor during the puerperium, it is inadvisable to await the spontaneous evacuation of the softened focus, for, even in case of a favorable outcome, the woman is exposed to weeks or months of illness, even if the acute danger to life, connected with the disintegration, has passed. At any rate the author advises that a woman who has undergone enucleation of a myoma be kept under careful observation during pregnancy and that, because there is danger of rupture of the uterus, the delivery be done in an institution.

Lymphangitic Form of Appendicitis.—Pribram calls attention to cases that are diagnosed as acute appendicitis which present the following symptomatology. The disorder begins suddenly with fever, general debility and pains chiefly around the umbilicus which occasionally have the character of umbilical colic and in other cases spread in the direction of MacBurney's point. The leukocytes are increased. If a thorough history is taken in such cases, a high incidence of throat inflammations is frequently detected. In some cases the abdominal symptoms following the operation progress and may terminate fatally. The operation discloses slight changes in the appendix but hyperemia of the cecum and of the last loop of the ileum and hyperemia and swelling of the mesenteric lymph nodes. Inflammation of the mesenteric layers and of the mesenteric lymph nodes with subsequent hyperemia of the serosa of the lower portion of the ileum predominates in the pathologic aspects of this disorder. The author applies to this disorder the name lymphangitic form of appendicitis. The patients who recover after the operation return later with complaints about renewed pains in the region of the umbilicus and fever. The leukocyte values are again increased and this relapse begins probably with a throat infection. These attacks may recur often, and, if a new operation is decided on, it discloses adhesions and scars in the mesenteric layers of the ileocecum, that is a mesenteritis. These so-called adhesion

operations are rarely successful. A removal of the tonsils, however, often results in the prompt disappearance of the symptoms. The author advances the following theory regarding the etiology. First there is an infection of the tonsils, usually with a streptococcus strain that has a lymphotropic tendency. During the acute angina the saliva with its bacterial content is swallowed, reaches the appendix and causes an inflammation of the appendix, which spreads to the mesenteric lymph channels, producing mesenteric lymphadenitis. The swollen lymph nodes in the root of the mesentery cause the pains around the umbilicus. Thus the umbilical colics are really pains in the lymph nodes. The author considers the umbilical pains a guiding symptom in the diagnosis of lymphangitic appendicitis and of mesenteric lymphangitis. If the condition has been definitely identified, the appendectomy may be postponed and a tonsillectomy may be done as soon as the anginal symptoms have subsided. If after that the abdominal symptoms persist, the appendix should be removed.

Determination of Inorganic Phosphate in Serum.—Müller stresses the importance of the inorganic serum phosphates for the diagnosis of rickets and for the estimation of its cure but points out that it has the disadvantage that comparatively large quantities of serum are required so that sinus or venous puncture is necessary. The methods of Bell-Doisy-Briggs and of Tisdall, although devised for small amounts of serum, have not found general application because of difficulties in the method. The introduction of rapid and intensively acting reducing agents and the use of the step photometer have eliminated many of the difficulties. After enumerating the requirements of a reagent, the author evaluates several and shows that eikonogen (aminonaphthol sulphonate) and amidol (diaminophenol hydrochloride) are most suitable but shows that, if certain factors are given proper attention, metol (methylpara-aminometacresol sulphate) may also be used. He gives a detailed description of the technic and a tabular report of some of the results he obtained with the three aforementioned substances.

Skin Resistance in Children.—Ackmann points out that the firmness, elasticity, tension and turgor of the skin permit conclusions regarding the general condition, the circulation and the renal function. Moreover, the age of a person causes changes in the skin, which become manifest in the factors mentioned. The skin of children reacts to changes in the organism more noticeably than that of adults. The author reports studies he made on the skin by means of the skin resistance meter devised by Jochims. The instrument measures the thickness of the skin fold, the total resistance and the retractility or the elastic resistance of the skin. The author made his tests on seventy-five children, including young infants and children ranging in age up to 14 years. He found that Jochims' skin resistance meter is suitable only for children up to 12 years of age. In older children the thickness of the skin fold and its tension exceed the capacity of the apparatus. Measurements made on different parts of the body differ considerably and, in order to obtain results that can be used for comparisons the tests should be made at the same site, preferably on the abdomen below the umbilicus. The author observed that the normal values change with the advancing age of the child. This is especially noticeable in young nurslings. During the first two months of life, the thickness of the skin fold changes from 4 to 5 mm., the total resistance of the skin fold from 150 to 180 Gm. and its retractility from 65 to 90 Gm. During the succeeding months the values

remain largely the same, thickness averaging between 5 and 85 mm, total resistance between 190 and 220 Gm and retractility between 90 and 110 Gm. Up to the twelfth year the values are approximately the following: thickness about 5 mm, total resistance from 200 to 230 Gm and retractility from 90 to 110 Gm. The thickness has a tendency to decrease, particularly during the periods of the growth in length, the increase in the total resistance is hardly noticeable, and the retractility increases slightly more. In children who are ill all values are reduced (reduction in the tension of the tissue, in the water content and in the fat layer). In convalescent children the gradual improvement is clearly noticeable in the values that are determined with the skin resistance meter. The total resistance reaches normal values sooner than the retractility. The author thinks that measurements with the skin resistance meter are valuable in determining the progress of convalescence and may eventually have a diagnostic value.

Prevention of Scarlet Fever Nephritis—Hiro emphasizes that the behavior of the liver plays a part in the pathogenesis of scarlet fever nephritis and that measures which protect the hepatic function are helpful in the prevention of scarlet fever. The opinion of some investigators that scarlet fever nephritis is more frequent in children who are kept on a milk diet probably arises from the fact that the milk diet with its high fat content exerts an unfavorable influence on the impaired liver and reduces its detoxicating capacity on the endotoxins and thus favors the development of nephritis. The author found that of the children with scarlet fever who were treated with a liver preparation 3 per cent developed nephritis, while of those who were not treated with it 13 per cent developed nephritis.

Silicosis in Porcelain Workers—Jonsson's report is based on roentgenologic studies on 236 porcelain workers. In the mildest cases there is only a diffuse increase in the perivascular connective tissue, but later on there appear nodules consisting of "dust cells" and hyaline connective tissue. To begin with these nodules are the size of a pin head, but they gradually become larger and attain a diameter of from 4 to 5 mm. They increase in number, and finally large indurated areas develop, which have a strong tendency to contract. In the later stages of silicosis emphysema develops between the fibrotic areas. A common condition following these pulmonary changes is hypertrophy and dilatation of the heart, especially of the right ventricle. The silicotic changes occur most abundantly in the middle parts of the lungs, i. e., in the inferior part of the superior lobe and the superior part of the inferior lobe. The roentgenogram in silicosis reflects rather clearly the pathologic anatomic changes. From the roentgenologic point of view it is usual to classify the cases of silicosis into three stages. Stage I is characterized by lesions which give a roentgenogram that shows delicate finely flecked shadows in the center of the lung fields and an increase in the fine shadows from the hilus. To stage II are assigned cases with larger nodular shadows and to stage III cases exhibiting large fibrotic areas and advanced contraction. The author's material is distributed over the different groups as follows: no signs of silicosis eighty-eight cases, suspected silicosis, eleven cases silicosis, stage I eighty-one cases silicosis, stage II, thirty-seven cases and silicosis stage III nineteen cases. In stage III the hilus shadows are usually no longer visible or else they are light

and vague. Various explanations have been given of this phenomenon. The author thinks that the disappearance of the hilus shadows in stage III is due to the fact that the silicotic dust gives rise to the same changes in the hilus as in the parenchyma, namely, extreme contraction. That this could contribute to a reduction in the hilus shadows seems probable. Moreover, owing to the extreme shrinkage in the pulmonary parenchyma, strong traction is exerted on all parts of the lungs in the direction of the center of contraction, which is generally situated in the posterior lateral parts of the lungs on a level with, or perhaps above, the hilus. The contraction causes extreme deformation of the lungs and of the mediastinum, and thus the pulmonary hilus is likewise changed in form and position. In all the severe cases of silicosis observed by the author, the elements which produce the normal hilus shadows are displaced. Under such circumstances the normal configuration of the hilus is entirely changed and is consequently difficult to recognize in the roentgenogram. The lateral picture is especially characteristic in silicosis. The changes are chiefly situated in the posterior parts of the lungs, corresponding to the areas of distribution of two specific bronchi.

Combined Diathermy and Roentgen Therapy of Malignant Tumors—Overgaard, after citing an earlier report in which it has been proved that transplantable tumors in mice can be influenced by diathermy, points out that it might be advisable to combine the action of diathermy with ray therapy. He made experiments on five groups of white mice. The animals were inoculated with mouse sarcoma. After the inoculated tumors had reached a suitable size (approximately 1 by 0.3 by 0.4 cm) the animals were divided into five groups. One group, the controls, were left without treatment, another group was treated with a moderate amount of roentgen rays, a third group was exposed to heat treatment in the form of diathermy, a fourth group was first treated with diathermy and on the following day with roentgen rays, and in the last group the order of the two treatments was reversed. The doses were relatively small and subtherapeutic, for these experiments were made only to determine the possible value of such a combination therapy and did not aim at the determination of the doses necessary for therapeutic action. The author discusses the results obtained in the different groups of animals. He gained the impression that the combination therapy provided essential advantages in that it combines a strong tumor destroying action with a relatively slight impairment of the surrounding tissues, that is, its selective action on the tumor is greater than if each treatment is employed separately. The order in which the two types of treatment are applied seems to be insignificant. This makes it appear unlikely that the first treatment merely effects a sensitization of the tumor cells but seems to indicate that the combination therapy exerts an inhibiting or damaging influence on two aspects of the vital functions of the cells.

Hereditary Hemorrhagic Angiomatosis (Osler)—Wilenius reports a case of recurring nosebleed with multiple telangiectases and hemangiomas in a woman, aged 58. In spite of the tendency to bleeding, no changes in the blood were demonstrable other than a secondary anemia due to the hemorrhages. A hereditary disposition to hemorrhages of simple dominant was established in three generations. The epigastric pains with melena in this case are ascribed to angiomatosis in the pyloric region. In early adult life cauterization of the telangiectases in the nose was ineffective, but recent cauterization together with general building-up treatment resulted in marked improvement.

ATHEROSCLEROSIS, THE IMPORTANT FORM OF ARTERIOSCLEROSIS, A METABOLIC DISEASE

ELEVENTH LUDVIG HEKTOEN LECTURE OF THE
FRANK BILLINGS FOUNDATION OF THE
INSTITUTE OF MEDICINE OF CHICAGO

TIMOTHY LEARY, M D
BOSTON

Though printed records of the lesions of arteriosclerosis first appear in the works of the anatomists of the sixteenth century, proof that the disease has existed from early times was disclosed by Shattock's¹ study of the mummy of Amenhotep II and by Ruffer's² observations in mummies dating from the eighteenth dynasty (about 1576 B C) to the twenty-seventh dynasty (about 525 A D). This has significance, since any agency brought forward as a cause of arteriosclerosis must meet the test of possible availability during a period of at least thirty-five centuries. From the records of early anatomists it is evident that the arterial changes were looked on as wholly incidental to age and therefore natural and not disease processes. Though specific descriptions of the lesions are found in seventeenth century publications, appreciation of the pathologic character of the process did not manifest itself until the eighteenth century. Morgagni in his *De sedibus et causis morborum* in 1761 included studies of the disease in smaller arteries, as well as the aorta, and associated chest pain with coronary hardening, which Crell had described in 1740. However, the disease was looked on as of purely pathologic interest, in spite of Heberden's concept of angina and Jenner's redemonstration of its relation to coronary hardening. With Virchow's studies of arteriosclerosis, which included recognition of the association of fatty substances with the lesions, clinicians began to consider seriously for the first time the clinical implications of the disease. Indeed, the clinical study of coronary sclerosis in America had its beginning only within the last twenty years, largely through the pioneer work of Herrick.

With reference to the cause of the disease, MacCallum³ said in 1922

Arteriosclerosis is one of those diseases difficult to explain because it develops so slowly through long years of life during which a great many possible causes have had an opportunity to affect the tissues. Our brilliant discoveries as to the etiology of disease come most readily when the transition from health to a pathological state is sudden and easily recognized by symp-

toms. Hence every conceivable idea has been expressed and tenaciously maintained with regard to this condition and many of them are so vague and ill-supported that it is wearisome to discuss them. None, however, is clearly demonstrated to have a definite bearing on the etiology of arteriosclerosis and we are quite as ignorant of the underlying cause as were our forefathers in the days of Morgagni.

In his textbook in 1932 MacCallum⁴ further said "We are at present, in spite of numerous theories, practically ignorant of the cause of arteriosclerosis." This reflects in general the opinion of pathologists here and abroad.

The title of this paper includes two propositions

1 That arteriosclerosis is the important form of arteriosclerosis. 2 That arteriosclerosis is a metabolic disease. Extensive discussion of the literature is rendered unnecessary by the review of the subject published by the Josiah Macy Jr Foundation.⁵

The human material for this study has been obtained from postmortem examinations of subjects in the medical examiner service of Suffolk County, supplemented by specimens of aortic and coronary lesions from the department of pathology of the Boston City Hospital, through the courtesy of Dr Frederic Parker Jr, and specimens of aortic lesions in children from the Children's Hospital, through the courtesy of Dr Sidney Farber.

The experimental material has been produced in cholesterol fed rabbits.⁶

ATHEROSCLEROSIS IS THE IMPORTANT FORM OF ARTERIOSCLEROSIS

What is arteriosclerosis? Virchow's studies drew attention to the fatty substances that are found so often in the lesions of the disease. Marchand named the condition atherosclerosis, from the Greek *αθηρη*, mush or porridge, because of the consistence of some of the fatty matter found in the disease. Aschoff⁷ extended and modified the observations of Virchow and divided the fatty processes into (1) the more or less physiologic and temporary deposit of fat in the intima of the young and (2) the definite disease process arteriosclerosis. The lesions arise constantly in the intima, though late extension to the media may occur.

In this discussion of arteriosclerosis, in agreement with other writers on the subject, the inflammatory forms of arteritis including those due to syphilis, tuberculosis, rheumatism, typhoid and other mycotic agents, periarteritis nodosa, thrombo-angitis obliterans and

other forms of obliterating endarteritis and repairing thrombosis are excluded. Hypertension per se is a distinct entity. It is of importance, probably through pressure, in favoring the initiation and progress of arteriosclerotic lesions. Only in this relation is its association included.

There remain only two forms of arteriosclerosis. Atherosclerosis, with the foregoing exclusions, is practically the only form of the disease arising in the aorta and its visceral branches. It is in particular the exclusive form encountered in coronary sclerosis and is the lesion occurring in the cerebral vessels and in the larger renal vessels.

In the peripheral arteries it is not rare to find in elderly persons, and particularly in elderly persons with diabetes, the form of medial sclerosis described by Mönckeberg.⁸ This lesion is marked by necrosis of muscle fibers in the media followed by calcification and often by bone formation. The process is essentially limited to the peripheral vessels, occasional examples being found in tumors and in the cerebellum. In Mönckeberg's sclerosis the calcification of the media with or without bone formation may produce complete ringing of the vessel and its conversion into a rigid tube. Though the calcification may occasionally extend into the intima and though the bony nodules may rarely narrow the lumen, the general effect of this form of sclerosis is to fix the caliber of the vessel in its largest capacity, perhaps because of loss of tonicity of the muscle layer. In the unmixed form the vessels are usually found dilated and with free lumens. When the lumen is considerably narrowed it is usually because of a superimposed atherosclerosis, arising independently in the intima. Disturbances of the circulation, almost without exception, are due to the engrafted atherosclerosis.

From all of the foregoing it may be concluded that atherosclerosis is the important form of arteriosclerosis.

ATHEROSCLEROSIS IS A METABOLIC DISEASE

With the growth of experimental methods, efforts were made to reproduce the lesions of arteriosclerosis in animals. Since stresses appeared to be factors in its production, various physical methods, destined to provoke stress conditions, were practiced but without definite results. Epinephrine was known to increase the blood pressure, and series of experiments with this agent were carried out. The resulting lesions were medial, with necrosis and calcification, resembling the Mönckeberg type of sclerosis. Recent work with viosterol produced similar results.

The constant association of fats with atherosclerosis led to dietary efforts to reproduce the lesions. To the Russian school belongs most of the credit for the production of intimal lesions in the arteries, first by the feeding of fatty foods and later by the feeding of rabbits with cholesterol.⁹ This work was not accepted by pathologists generally. Criticisms were made that the rabbit was not a suitable animal for experimentation in arteriosclerosis, that the results were due to the use of perverted diets, that the lesions described did not correspond exactly to the lesions of human atherosclerosis. The condition produced in the animal was referred to, often contemptuously, as the "cholesterol disease of rabbits."

My interest in arteriosclerosis arose out of observations that as a class persons suffering from alcoholism appeared to show a lesser degree of atherosclerosis than their ages would justify. A study of the lesions of coronary sclerosis, fatal examples of which disease are common in my material, led to the following conclusions:¹⁰

- 1 Atherosclerosis is a disease and not the inevitable consequence of age, since it appears in the young and may be highly selective in its localization.
- 2 The characteristic lesion in youth is a fibrosis associated with the presence of lipid cells, which do not accumulate in large aggregations, because of the growth of the fibrous tissue.
- 3 The characteristic lesion at older ages is the accumulation of large collections of lipid cells with minimal connective tissue support. As a result of poor nutrition massive necrosis occurs, giving rise to so-called atheromatous "abscesses."
- 4 The standard cause of death in the young is thrombosis following subendothelial necrosis which extends to the endothelium.
- 5 The standard cause of death in the older group is the rupture of an atheromatous "abscess" into the lumen, usually followed by thrombosis.
- 6 The process is primary in the intima, stresses favor the localization of the lesions, morphologic lesions in the elastica and media occur secondarily.
- 7 The disease is not inflammatory in origin.

A comparative study of the lesions of human coronary sclerosis and experimental coronary sclerosis in the rabbit led to the following conclusions:¹⁰

- 1 The lesions of human atherosclerosis can be reproduced in the rabbit by the feeding of cholesterol.
- 2 The fibrosis which is characteristic of human coronary lesions in the young is the characteristic lesion in cholesterol atherosclerosis in young rabbits. Fibrosis is therefore a reaction of youth and not of species.
- 3 The evolution of the lesions through lipodosis, lipid cell formation and fibrosis, more rapidly produced in experimental animals, can be followed in greater detail in these animals than in human lesions, in which progress is so slow that the stages in the progression are distinguished with difficulty.

The results of this work did not clearly explain why in the young the response to the presence of cholesterol was fibrosis, while in the old little or no fibrosis appeared.

Attention was then centered on the lesions of the human aorta. The average physician mentally pictures atherosclerosis from his memory of the gross lesions he has seen in the aorta. Moreover, the aortic lesions are so varied that it is difficult to believe that a single agent should produce so kaleidoscopic a series of processes. Exhaustive detailed studies of the histology of these lesions had been carried out, but the reason for their variety had not been disclosed.

The Inhibition of Lipoid—All investigators agreed that the picture begins with the appearance beneath the aortic endothelium of phagocytic cells containing fatty material. The first question suggesting itself was the method by which this lipid, probably imbibed, reached the standard sites in the aorta. Edema of the intima occurs not rarely with swelling and stretching of the endothelium. This could well favor the introduction of foreign material. Whether it is the actual forerunner of lipid deposit is debatable. The massive forms of edema, covering large areas of the aortic surface, can hardly be associated with the beginnings of lipid infiltration, since no fatty lesions extending over such great areas are found. Moreover, this edema has the appearance of a terminal process arising shortly before death and usually in toxic cases. Minor degrees of

¹⁰ Leary Timothy. Experimental Atherosclerosis in the Rabbit Compared with Human (Coronary) Atherosclerosis Arch Path 17:455 (April) 1934

the process might account for the imbibition. Warren¹¹ suggests that the high sugar concentration and the great fluctuation in sugar concentration in the blood of persons with diabetes could possibly lead to swelling of the intimal ground substance through changes in osmotic pressure and thus favor lipid imbibition. Nuzum and his associates¹² stressed the possible importance of high protein diets in favoring intimal damage. The most striking evidence indicates that high blood cholesterol is the standard factor from the dietary standpoint in the causation of atherosclerosis.

The importance of stresses in leading to the selective localization of atherosclerotic lesions in the aorta has been much discussed. The favorite site of the process over the posterior wall about the lines of the intercostal orifices is in the most firmly anchored portion of the vessel. The selection of sites about the orifices of aortic branches can be explained as the result of variation of stresses as the contracting and dilating waves of the free wall come up against the obstructions that arise at the orifices. The relative freedom of the ascending arch from lesions is discussed later in the paper. In general the close relation between hypertension and arteriosclerosis emphasizes the importance of stresses. Based on this connection and the deduction that unusual stresses must occur in the coronary arteries in congenital heart disease, an examination was made of the left coronary arteries in eight such hearts, which disclosed atherosclerotic lesions in five of them.

The Phagocytic Cells—The next question is the source of the phagocytic cells that take up the lipid. They may be monocytes from the blood. They are not histiocytes that wander in from neighboring tissues, because evidence of such invasion is lacking. I am inclined to believe with Klotz and Manning¹³ that they originate from the subendothelial connective tissue. In experimental cholesterol lesions a marked proliferation of this tissue sometimes occurs at sites where lipid infiltration is beginning.

The phagocytic cells found in atherosclerosis show in the human being little tendency to wander beyond the limits of the vessel. In the experimental rabbit under acute massive dosage, extension through the wall is common in the smaller vessels. The perivascular lymphatics may be crowded with the cells, and the regional lymph nodes may contain them. Blood distribution probably also occurs, since the cells are found in numbers in blood vessels, notably in the spleen, in the experimental animal.

The studies of Opie¹⁴ and others have demonstrated the presence in the mononuclear exudative cells of a proteolytic enzyme, which is most efficient in an acid medium, unlike the enzyme of polymorphonuclear leukocytes, the greatest activity of which is shown in a neutral or slightly alkaline medium. In addition, an erepsin-like enzyme is found in leukocytic exudates, which splits proteoses and peptone into amino acids and tryptophan. Mudd¹⁵ and others in a review of phagocytosis deplore the lack of studies on intracellular lipid activities. The extensive studies on the Niemann-Pick, Gaucher and Hand-Christian diseases are unsatisfactory in this respect.

The occurrence of cholesterase widely in the organs, tissues and fluids of man and animals and the finding of cholesterol crystals in relation to necrotic tissues and exudates bespeak the activity of such an ester splitting enzyme. Its function is limited to the hydrolysis of cholesterol esters in digestion and perhaps to their resynthesis.

Physical Characteristics of Cholesterol—Cholesterol and certain of its compounds have physical characteristics that permit of tracing the substance to a degree in the tissues. In the ester form seen in the arteries, cholesterol occurs in drops which stain like fats with the sudans and which are anisotropic, the so-called fluid crystals of Lehmann. Under the polariscope they exhibit dark Maltese crosses, producing a tetrad-like appearance. The solid crystals, whether in the typical oblong plates with a notched corner or in needle forms of the esters are doubly refractive.

The cholesterol esters in the surface lipid cells of aortic lesions are evidently in very unstable equilibrium, since in tissues fixed in solution of formaldehyde they precipitate, the crystalline masses distending and frequently rupturing the cells containing them. The precipitation of cholesterol in formaldehyde fixed tissue permits of a visualization of the massive content of the lipid within these cells, particularly with polarized light. Freezing of fresh tissues may have the same effect as fixation in solution of formaldehyde, while heating of the sections may cause the crystals to disappear. On refreezing, however, the solid crystals again manifest themselves, though the total crystal deposit may not be reproduced except by freezing at very low temperatures. Staining with sudan tends to overcome anisotropism to a certain extent. Unstained sections should be studied for complete evidence of anisotropism.

Aortic Lesions—(a) *Youth*. Whether the cholesterol is in solid or fluid crystal form, the globular cells showing marked anisotropism are limited to the surface subendothelial layer in the aortas of younger persons. Below this layer appear ameboid fat-containing cells, with branching processes, in a loose textured connective tissue arising from stimulation of the subendothelial layer. The fat in these deeper cells is present in drops, which are not in general anisotropic. Under the polariscope in unstained specimens some of these cells are seen to contain small anisotropic solid crystals, which tend to be smallest in the deepest cells. Many of the cells show no anisotropic substance even in the unstained section. This loss of anisotropism is associated with division of the enclosed fatty material into smaller and smaller droplets. In regions where the process shows further progression, cells occur in which the droplets are few in number and certain of them appear to have freed themselves completely from the engulfed lipid. Finally, in adjacent areas where the cells have freed themselves of cholesterol the only material staining with sudan is in the finest conceivable form (Bloor's fat dust) in the wavy bundles of the intercellular fibrillae.

The amount of connective tissue produced may be small and no gross scarring results. However, I have never seen a lesion in which cholesterol esters were contained within lipid cells in the young in which some connective tissue was not produced.

This is at variance with Aschoff's thesis that in youth lipid deposits in the aorta are harmless and merely mechanical, the process being reversible and the lipid

disappearing without trace (atheromatosis) In the experimental animal, lipoid is deposited in the early stages in free form beneath the endothelium before phagocytosis occurs In this state it is a bland substance awakening no activity in neighboring cells In human lesions a similar deposit may occur not only beneath the endothelium but in deeper layers, even in the media My observations, however, indicate that visible yellow lesions in the aorta at any young age are constantly associated with phagocytosis and stimulation of connective tissue growth

In young persons a rather diffuse infiltration of the intima over large areas is often found in the form of a pale yellow deposit with pinpoint deeper yellow foci Microscopically such a lesion shows focal collections of globular lipoid cells just beneath the endothelium forming the bright yellow points, and ameboid cells carrying lipoid distributed more widely through a loose textured connective tissue responsible for the diffuse pale yellow coloring

(b) *Adult Life* As one grows out of the period of youth, the metabolism of cholesterol within lipoid cells tends to grow less efficient Though connective tissue growth is stimulated, the metabolism is often slowed, the connective tissue secretes collagen, and the lipoid cells are frequently hedged in by scar tissue They lose their branching processes and become globular or flattened ovoid masses, retaining marked anisotropism, in the interstices of the scar tissue The cells that have migrated most deeply, i. e., farthest away from the nutritive supply from the intima, tend to undergo necrosis, and the lipoid from many cells together with tissue fluids gives rise to one form of atheromatous "abscess" in which no living cells are found These lie in the deep layers of the intima directly above the media

Sections of atherosclerotic lesions in middle life reveal processes in which the color and consistence are dependent on the relative amounts of lipoid and scar tissue The newest processes are bright yellow and rich in lipoid cells, largely at the surface, the older are paler yellow or white, depending on the amount of scarring Evident lateral spreading from small unit lesions has produced large pale yellow raised foci, the long diameter of which corresponds to the long diameter of the vessel The paler yellow lesions are relatively rich in lipoid cells with anisotropic contents, globular but fewer near or at the surface, with some evidence of the tendency to branching processes in the next deeper layer, and definite formation of older connective tissue, together with necrosis and mixed lipoids and fluid in the deepest layer The whiter scarred foci show usually, even on gross section, a deeply placed yellow layer, which the surface scar tissue has obscured Microscopically the scar tissue may still contain isolated ovoid or flattened lipoid cells in varying numbers The deepest intimal layer, yellow as seen on gross section, is made up of a pasty mixture of lipoids and fluid or is a mass of necrotic tissue permeated with fat dust

Rarely a pure healed scar is found, usually a survival from a more youthful period Many of the grossly pale scars show on microscopic examination varying amounts of material staining with sudan IV in the depths

(c) *Old Age* In older persons the ability of the phagocytic cells to metabolize cholesterol grows less or disappears As a result, lipoid cells the contents of which are strongly anisotropic become massed in the

intima, with minimal reticular strands separating groups or single cells New vessels are formed rarely if at all Massive necrosis may occur associated with freeing of the cholesterol in crystalline form The more soluble lipoids that assist in holding it in solution are presumably absorbed Rupture of such atheromatous "abscesses" through the thin covering, made up of endothelium alone or with a small amount of connective tissue, is common The cavity becomes filled with blood, the disintegration of which gives rise to pigment deposits The delivery of the softened contents of an atheromatous "abscess" into the aortic blood stream occasions no serious consequences The mass becomes finely divided and mixed with the blood The persistence of the semifluid contents as a more or less coherent mass, capable of obstructing, is possible only in smaller vessels, such as the coronary arteries

The Nutritive Factor—There appears to be a close association between local nutrition and metabolic activity of lipoid cells Even in individuals in the thirties, and sometimes at younger ages, a delay in freeing the tissues of cholesterol and the formation of surface scar tissue in the lesion will result in evidence of failing metabolism in the deep layers In many advanced lesions with almost complete scarring the dense connective tissue in the depths of the lesion undergoes necrobiosis, becoming permeated with fat dust and larger fat globules It is recognized that except when associated with syphilitic aortitis the arch of the aorta, particularly the ascending arch above the ring, tends to be much freer from atherosclerotic scars than the rest of the vessel Yet early lipoid deposits in the form of small yellow mounds often occur in the arch, frequently in large groups These lesions are cared for apparently by relatively rapid removal of the lipoid and minimal scarring even in older individuals Spreading of the lesion from these small yellow mounds to form larger foci, a common picture in the aorta elsewhere, is exceptional in the arch

Calcification—In atherosclerotic lesions calcification is always a late, one may say a terminal, process It appears earlier in aortic than in coronary lesions in general Unlike the calcification in Mönckeberg's sclerosis, which occurs without evidence of visible fat, atherosclerotic calcification tends to be intimately associated with lipoid In some lesions with slow necrobiosis the deposit of lime salts appears to arise in relation to the breaking down of the nuclear protein of dying cells In some of these cells, lipoid droplets and globules of calcium and fat can be found within the same cell body In the deposit of calcium in regions of massive coagulation necrosis, usually in irregular "geographic" areas, globules with an affinity for acid dyes are found along the border of the lesion in the still living tissue, while in the necrotic region the similar globules have an affinity for basic dyes Plaques and solid masses of calcic deposit appear to arise from the fusion of these globules into larger masses The calcified plaques in the aorta tend to develop toward the surface and ultimately in many cases are separated from the lumen by a layer of endothelium with little or no connective tissue

Vasa Vasorum—The influence of the vasa vasorum in connection with the lesions of atherosclerosis is relatively unimportant Even in comparatively large foci the nutrition seems to depend on imbibition through the endothelial layer This probably in part accounts for the diminished efficiency of the handling of cholesterol

as the thickness of the lesion increases. In some of the older scarred lesions, notably about orifices of vessels, such as the intercostals, evidence of activity of the vasa vasorum is found, but always as a late phenomenon.

To recapitulate, the early lesions of arteriosclerosis are marked by (1) the phagocytosis of imbibed cholesterol esters by cells probably of local origin, (2) invasion of the deeper layers of the intima through ameoboid activities of these cells, accompanied by (3) a loss of anisotropism of the contained cholesterol and (4) dividing of the lipid into fine droplets, (5) stimulation of connective tissue growth and (6) disappearance of the lipid with minimal scarring.

The close resemblance between this process, as seen in the young, i. e., the division of fatty material into finer and finer droplets followed by its disappearance, to the system of fat absorption in the intestine, and of fat injected into the transparent tadpole's tail, as observed by the Clarks,¹⁰ is manifest.

A definite progression in the loss of anisotropism from the large globular surface cell, surcharged with anisotropic lipid, can be followed through the upper layers of ameoboid cells still containing anisotropic crystals to cells the contents of which reveal no anisotropism. The combined loss of anisotropism, division of the lipid and its local disappearance furnish morphologic evidence of a cellular cholesterol metabolism that has been lacking up to now.

In the very old this process of cell metabolism is lost, lipid cells do not become ameoboid, and their contents do not lose their anisotropism and are not divided into fine droplets. Lipoid cells tend to occur in large masses, which undergo necrosis, freeing cholesterol crystals and forming atheromatous "abscesses."

In the middle period of life, lesions are found representing imperfect metabolism of the contained lipid in recent lesions, with some formation of connective tissue, which tends to become scar tissue near the surface. There is less evident loss of anisotropism of the lipid contained in the cells. In the depths of the lesion there is a marked tendency to form atheromatous "abscesses." In this and the older period, scarred and intermediate processes that have persisted through years are an important part of the picture, as are calcified plaques.

As we grow old our aortic linings come to be beset with scars, pits, mounds and calcified monuments marking the sites of unsuccessful local battles with cholesterol.

The aortic picture described is of course only a reflection of a general disturbance in cholesterol metabolism.

GENERAL DISTURBANCES IN CHOLESTEROL METABOLISM

The rabbit must possess a metabolic system to synthesize the cholesterol needed by its cells, since it ingests only plant sterols, which are not absorbable in most animals. This metabolic system is, however, evidently weak, just adequate to care for the animal's needs for the substance.

Atherosclerosis can be produced readily in the rabbit by overwhelming this weak metabolic system through feeding cholesterol. The same procedure, i. e., the overwhelming of the cholesterol metabolic system, was unintentionally carried out in human beings by the use of high fat diets in diabetes in the decade 1920-1930, and the results were just as definite as those obtained

in the experimental rabbit. It was reasoned that fat could be substituted for carbohydrates and thus spare the inefficient carbohydrate metabolism in diabetic patients. The reasoning was good. Unfortunately the simplest method of increasing fat was to add cream, butter and eggs, all wholesome foods but potent sources of cholesterol, to the dietary. The effects of the excessive cholesterol diet manifested themselves in an increase of arteriosclerosis, even in children, and xanthomas were more common in the skin. Shields Warren¹¹ said:

Whether the increased prevalence of arteriosclerosis in diabetes is due to the disease itself or to methods of treatment of the disease, the importance of the problem is such that it cannot be disregarded. I have yet to see at autopsy a diabetic or to read the autopsy of a diabetic whose disease has lasted five years or more, free from arteriosclerosis, regardless of age.

The diabetic has not only more than his share of arteriosclerosis, but it falls to his lot ten or twelve years earlier than to the non-diabetic.

White¹² records roentgen evidence of calcification of vessels of the legs in nineteen of 106 children, one at 4 years of age, two at 6, three at 7, one at 8, four at 9, two at 10, two at 11, two at 12, one at 13 and one at 14. Among these the daily diet included more than 100 Gm of fat in all but two, and two received 150 Gm daily.

The reverse of this picture under low fat diets, is indicated by recent reports from the same clinic (Jos' n) in which Warren's and White's observations were made. Roentgen shadows of calcified leg arteries in children are no longer obtainable, and xanthomas do not occur. Rabinowitch reports that already there is evidence of less atherosclerosis in adult diabetic patients in Montreal.

On all the evidence presented there can be little reasonable doubt that arteriosclerosis is a disease arising out of inadequacy of the cholesterol metabolism. Stresses are factors in the localization and progression of lesions. Other secondary factors may play a minor part.

CHOLESTEROL

As its name indicates, cholesterol is an alcohol, a hydro-aromatic secondary alcohol, but it possesses the power of uniting with fatty acids to form esters. It is one of the most complex substances occurring in the animal body. It is relatively insoluble, its best solvents being the fat solvents. It is highly resistant to the action of enzymes, whether of animal, vegetable or bacterial origin. Cholesterol is found in every animal cell. It and ergosterol (which is associated with it in minute amounts) are the only sterols found in animal bodies. It is isomeric with or closely allied to the plant sterols, some of which differ from it only in molecular arrangement. This difference appears to be the factor preventing the absorption of plant sterols, cholesterol (with ergosterol) being the only sterol which is absorbable.¹³ In the animal body it is closely associated with the fats, being found in the unsaponifiable residue following extraction by fat solvents.

Recently much attention has been paid to the functions of cholesterol. Starling's¹⁴ concept of its functions within the cell is as follows:

In view of the great stability of this substance when exposed to the ordinary mechanisms of chemical change in the body, it seems probable that the part played by cholesterol is that of

a framework or skeleton, in the interstices of which the more labile constituents of the protoplasm undergo the cycle of changes which make up the phenomena of life

Bills,²⁰ in a review of the physiology of the sterols, says

There are groups of physiologically important substances which are fundamentally sterols in structure, although they are generally classified according to their function. Among these are the bile acids and certain cardiac poisons, sex hormones, venoms and vitamins

In digestion, cholesterol is believed to function as a conveyor in the absorption of fats. The white matter of the brain is rich in cholesterol, the organ containing about one ounce of the substance. Its function appears to be to serve as an insulating medium in the myelin sheaths. It forms 19 per cent of human skin fat. Cell membranes are believed to be rich in cholesterol and phosphatides, which control cellular permeability and membrane equilibrium. In this relation it is known that cholesterol is an active antihemolytic agent. It opposes the hemolytic action of saponin, solanin, cobra venom and tetanus toxin.²¹ Sterols are present in seeds, pollen, spores, ova and sperms, suggesting some peculiar need for sterol by the developing embryo. The formation of cholesterol ester from free cholesterol in the third week of incubation of chick embryos, associated with calcification of the bones, has suggested that the phosphorus for calcification comes from the breaking down of lecithin, and the fatty acids thus liberated combine with the cholesterol. Cholesterol has been shown to oppose flocculation within the blood stream, which, according to Lumiere's theory, is the cause of anaphylactic shock.

A large part of the adrenal lipoids is made up of cholesterol compounds. When the adrenal cortex is robbed of its fats in fatal toxic or septic conditions, the anisotropic lipoids seem to be lost to a greater extent than the isotropic fats. Cholesterol, independently of ergosterol, contains provitamin D, susceptible of irradiation. The sex hormones, according to the formulas of Butenandt and others,²² are related to and probably derived from sterols. Ruzicka and others²³ have succeeded in producing androsteron, the testis hormone of Butenandt, from cholesterol. Recent work by Dodds and Cook²⁴ indicates the close relationship chemically between the sex hormones and certain carcinogenic hydrocarbons, which are also degradation products of sterols. Campbell,²⁵ discussing the apparent immunity to cancer in mice produced by placental and embryonic skin extracts, said

If oestrin (the female sex hormone) is responsible, directly or indirectly, for production of natural immunity, we should expect cancer to be most prevalent when the production of oestrin ceases. This is the case, at any rate, in the female, since cancer is most prevalent after the menopause.

Though knowledge of the sterols is still limited, it is rapidly growing under the stimulation of new evidence of the relation of these substances to human life and disease. From every point of view, cholesterol is one of the most important substances present in the body.

Knowledge of cholesterol metabolism within the human body is limited. Because the material tends to be stored, doubt has been thrown on the results of dietary studies of human ingestion and excretion of the substance, the possible stored cholesterol being an unknown quantity. Schoenheimer and Breusch²⁶ ingeniously overcame this difficulty in estimating the powers of mammals to metabolize cholesterol, by using mice, whose whole bodies could be analyzed. Their results indicate that the mouse can synthesize cholesterol on a cholesterol free diet. On a diet containing moderate amounts of cholesterol, less was synthesized. When large amounts of cholesterol were fed, a considerable part was destroyed. The disappearance of intimal deposits of cholesterol from the aorta of young adults during the period of fat famine in Germany following the war suggests that the human cholesterol metabolism may have reserve powers in times of need.

That man can synthesize cholesterol is probable. The indications are that he does not, all of the cholesterol which he needs being ingested. Milk, eggs and pork fats are the important sources in human diet. The presence of cholesterol in large amounts in seeds, pollen, ova and spores has been referred to as indicating special needs of the embryo for this substance. Egg yolk, which is rich in cholesterol, is intended for the embryo. Milk is intended for the infant. Man is the only animal that ingests eggs and milk during a lifetime. Man is also the only animal that dies in early life from coronary sclerosis and acquires atherosclerosis almost universally in advanced life. It is interesting to note that man's closest rivals in this respect are the birds, as shown in Fox's²⁷ valuable studies of the disease in lower animals and birds. Birds, particularly domestic fowls, must possess remarkable powers to metabolize and presumably to synthesize cholesterol. The amount contained in the yolk of hen's eggs almost daily produced, is very great. Perversions of this metabolic system might well account for this rather deadly form of rivalry of the bird with man.

ATHEROSCLEROSIS A METABOLIC DISEASE

As one studies atherosclerosis, one is impressed by its general resemblance to the other metabolic diseases, and particularly to diabetes. As in diabetes, marked variations in susceptibility are evident in the experimental animal and seem to exist in man. As in diabetes, the inheritance of a weak cholesterol metabolism appears to lead to early death from coronary sclerosis. There are families in which coronary disease is the standard form of death. As in diabetes, advancing age with growing inefficiency of the cholesterol metabolism is associated with more frequent manifestations of the disease. The ability to prevent cholesterol deposit or to diminish the amount of atherosclerosis produced in cholesterol fed rabbits by the use of thyroid extracts²⁸ suggests the relation of cholesterol metabolism to this internal secretion. Finally, a familial inheritance which seems to be dependent on a general inferiority of the metabolic systems may manifest itself in individuals of such a family in the form of diabetes, obesity, arteriosclerosis, gout or combinations of these.

This discussion of atherosclerosis, dealing as it does with the harmful effects of cholesterol overdosage, can

not be closed without calling to attention the fact that cholesterol is an important food substance, as necessary as the carbohydrates, fats, proteins and mineral elements of the dietary. All the cholesterol needed by the cells of the human body is ingested. Milk and eggs are wholesome foods to which the human race is accustomed and which are necessary sources of cholesterol. As one advances in years, the needs for this substance appear to grow less. In general, apart from susceptibles, it is the abuse, the overeating of these foods, as is true in the case of other food substances, that is likely to produce disease.

ALLERGY AND CATARACTS

RUBY K DANIEL, MD

Fellow in Ophthalmology the Mayo Foundation
ROCHESTER, MINN

The term "allergy" means a condition of unusual or exaggerated specific hypersensitivity to a substance which, under like conditions and in similar amounts, is harmless for the large majority of members of the same species. Allergic diseases are divided by Coca¹ into these four classifications: "(1) atopy (hay fever, asthma, eczema group), (2) contact dermatitis, (3) serum allergy, and (4) drug allergy." More than one type may be present in the same individual as well as among members of his family.

Bray² has diagramed the integral factors producing the allergic state and listed the methods of entry of the specific antigens, allergens or causative agents by the following routes: "(1) inhalation, (2) ingestion, (3) injection, (4) infection and (5) contact." Catalyzing nonspecific factors, he stated further, are "(1) dietary, (2) environmental, (3) nasal, (4) toxic, (5) psychic, (6) endocrine, (7) physical, (8) chemical and (9) mechanical." Hereditary predisposition or damage to tissue or both are the rule, although occasionally an acquired predisposition must be admitted. If both parents happen to be allergic, the majority of the offspring will show some manifestations of hypersensitivity, and it is likely to appear at an earlier age than in the parents.

From 1 to 5 per cent of human beings are spontaneously allergic in some way, and their reaction largely occurs in the skin and in the conjunctival, respiratory and gastro-intestinal tissues, which of course are the principal coverings of the exposed surface of the body. This hypersensitiveness ranges from a mild reaction, which may go unnoticed for a long time, to such a severe reaction that it threatens life. Fortunately the vital centers are rarely influenced to extreme degrees. However, further studies have indicated a much wider involvement than was first recognized. Allergic migraine is only one instance of such deduction with evidence for its substantiation.

The endocrine system frequently plays a definite role in the symptomatology, and epinephrine, thyroid, parathyroid and pituitary extracts have been of value in the treatment in special cases. The sympathetic nervous system largely activates this group of glands, and hence

it is difficult to know whether these glands influence the nerves or the nerves alter the secretion of the glands in this particular link of the chain. Perhaps the answer to the problem of allergy is to be found in physiobiochemical equilibrium.

It has long been observed that conjunctival hypersensitivity is not an uncommon finding among patients who have the allergic manifestation of asthma, hay fever or vasomotor rhinitis. Vernal catarrh is classed in the allergic group of reactions and has a high incidence of accompanying allergic phenomena.

Wesseley in 1911 called attention to the fact that keratitis in certain forms can be an allergic manifestation. Episcleral, scleral and uveal changes have been reported to be allergic. The crystalline lens is not exempt from the influence of allergens, which may be causing changes in other tissues of ectodermal origin. The ectodermal epithelium of the ciliary body is responsible for the formation of the aqueous fluid, which in turn nourishes the lens and carries away the waste products. A fine change in the function of these epithelial cells of the ciliary body, in the content of the aqueous fluid or in the level of permeability and selectivity of the capsule of the lens can readily be reasoned to interfere with the efficient metabolism of the lens and its transparency, thereby producing a cataract in an otherwise normal eye.

In 1868 Rothmund³ reported the occurrence of cataracts in connection with changes in the skin. Andogsky,³ a Russian ophthalmologist, used the term "cataracta dermatogenes" to classify a case in which a youth had bilateral cataracts and a simultaneous skin eruption, he felt that these conditions had a common underlying factor. Löwenstein,⁴ Gault⁴ and others found a number of cases of bilateral cataract associated with neurodermatitis. Kurz⁵ reported a case in which opacities of both lenses, associated with eczema, occurred in a person aged 21. Davis⁶ reported the case of a girl, aged 15 years, who had eczema and bilateral cataract. These as well as the other opacities reported occurred in previously normal eyes. The form of opacification largely resembled the anterior stellate cataract, proceeding from the capsule of the lens without further changes in the eye. These cataracts were always bilateral and occurred principally in the young adult as a rather significant accompaniment of changes in the lens and skin. The common origin of the epithelium of the skin and the epithelium of the lens was thought by Davis to correlate the phenomena, and attempts were made to explain the changes on a basis of the endocrine glands, sympathetic nervous system and calcium level, and in numerous other ways. That there is an element of endocrine function involved is often obvious, but as to the evaluation of each particular gland as a causative factor or catalyzing agent, much remains to be proved.

REPORT OF CASES

CASE 1—A girl, aged 17 years, admitted to the Mayo Clinic Nov 9, 1934, complained of extensive atopic eczema and marked decrease in vision due to rapidly developing cataracts. The family history was significant from an allergic standpoint. The mother had suffered from hay fever, the father had had vasomotor rhinitis, a maternal uncle had had fever, and a grandmother had had eczema of the skin of the hands.

Involvement of the patient's skin had first occurred in the form of a mild flexural eczema at the age of 18 months. When

Read before the Section on Ophthalmology at the Eighty Sixth Annual Session of the American Medical Association Atlantic City, N J June 13 1935

she was 4 years old she had handled a dyed Easter egg, and immediately following this she had had marked dermatitis and a "gelatinous-appearing" edema of the bulbar conjunctiva of both eyes. From the age of 1 to 7 years treatment had been necessary for recurring bronchitis, and from the age of 6 to 13 years she had had frequent though mild attacks of urticaria.

At the onset of menstruation, when the patient was 13 years of age, there had been an extensive exacerbation of the lichenified eruption over a much greater area than had previously been involved. Eighteen months later she had observed dimness of the vision of the left eye, and four months later she had noted a gradual but similar decrease in the vision of the right eye. Examinations had revealed bilateral immature cataract. In a year these cataracts had developed, and vision had been reduced to such an extent that she was only able to count fingers with her right eye and to distinguish movements of objects with her left eye. Extensive skin manifestations and allergic rhinitis had continued with brief remissions and longer exacerbations depending largely on the exposure to the many articles of food and environmental factors to which she was sensitive. Eggs, milk, house dust, ragweed, corn pollen, cottonwood, silks and dyes seemed to cause the most marked reactions. Basal metabolism at one time had been recorded as -18 . Thyroid extract had been given, without benefit, and it had been discontinued when it had seemed to increase her "nervousness."

On examination at the clinic the patient appeared well nourished and was of normal physical development. She had bilateral mature cataracts, allergic rhinitis, and extensive hyperpigmented red, lichenified, atopic eczema over the body, face and arms. Vision was limited to ability to see moving objects with the right eye and to see light with the left. The skin of the lids, which corresponded closely to that of the face, was thick and leathery and was bordered by broken stubby cilia. The palpebral conjunctiva appeared thickened but otherwise normal. The corneas were clear, the anterior chambers were normal, and the pupils were round and equal and reacted well to light. The irises were normal. Both lenses had a homogeneous grayish white appearance that obstructed all view of the fundi. Transillumination of the globes was uniform.

CASE 2—A girl, aged 17 years, admitted to the clinic Feb. 25, 1935, complained of marked recurrent eczema. She said that her mother had had hives and had been subject to a migrainous type of headache. Since the age of 2 months the patient had suffered from a mild flexural recurrent eczema. At the age of 11 years the first marked exacerbation had occurred and asthma had developed. One and a half years prior to her admission to the clinic the eczema had become generalized and the eyelashes and eyebrows had broken off, leaving them stubby. Exposure to silk, animal hair or eggs seemed to cause the most severe reactions.

Physical examination revealed an extensive, hyperpigmented, red, lichenified eczema on the arms and legs, body and face. This case was recognized as closely resembling case 1, both as to the age, sex and history of the patient and as to the manifestations. The patient was sent for a slit lamp study of the lenses, although there were no eye complaints. Previous examinations of the fundi and retinas had been negative, with the exception of a slight astigmatic error. Vision was 6/6 in each eye. The broken-off cilia and brows were noted as well as the thick leathery scaling skin of the lids, which corresponded to that of the rest of the face. The conjunctiva appeared normal. Examination of the globes externally and of the fundi gave entirely negative results except for a faint, grayish, veil-like, anterior, central and cortical opacity in the right lens.

Two and a half months later during which time, incidentally, the patient had suffered acute exacerbations of the allergic manifestations, there was observed a slight but definite increase in the opacity, and a faint brownish tint appeared instead of the grayish tint that had first been noted. The margins of the opacity were changed in shape and the points extended out as limbs or dendrites, showing an actual progression.

Skin reactions of both this patient and of patient 1 were markedly positive to their respective known allergens, as were also the reactions in normal individuals used for passive transfers.

CASE 3—A man, aged 35, admitted to the clinic Oct. 27, 1934, complained of recurrent eczema of the face and hands and gradually decreasing vision in each eye.

Five years previously the patient had noticed for the first time a small, localized skin eruption in the right temporal region. This patch of scaling, redness and itching had been intermittent. Approximately two years later a symmetrical and similar eczema-like patch had been present intermittently in the left temporal region. One year prior to his admission to the clinic and following a change of residence a severe flare up of this same type of dermatitis had recurred after he had eaten shrimps, and on this occasion it had involved the entire skin of the face. This eruption had been characterized by blisters, small fissures, excoriation and a moist watery exudation and had lasted over a period of two months. Following this a slight but definite decrease in vision had been noticed in each eye. The patient had consulted an ophthalmologist, who had made a diagnosis of bilateral cataract. Examinations of the eyes prior to this time had been entirely negative.

On examination at the clinic the patient appeared well nourished. Eczematous dermatitis was present on the face and neck, and there were small patches of excoriations over the trunk, back and buttocks. The skin of the hands and face, including the eyelids, was excoriated, dry and scaling, thickened and leathery. Skin tests confirmed the allergic reactions to shrimp and nickel. The eyelashes and brows were broken off and stubby.

Vision in the right eye was 6/20 and in the left eye 6/15. With refractive correction the vision in each eye was improved to 6/12. The palpebral conjunctiva appeared thickened but otherwise normal. The bulbar conjunctiva was normal and the cornea clear. The anterior chambers were normal and the irises normal. The pupils did not react well to light (the patient had been instilling a 2 per cent solution of homatropine once daily to facilitate vision). Each lens showed a small, gray, central, oval, elevated plaque in the capsular region, measuring 3.25 by 2 mm in the right eye and 1.15 by 2 mm in the left eye. With the slit lamp the cortex and nucleus appeared clear. The posterior capsular region appeared to have a similar process. The fundi were normal.

CONCLUSIONS

The three cases here reported not only fall into the group "opacification of the lens in young adults accompanied by skin manifestations" but further, by virtue of the history and the positive allergic reactions observed, could also justify the term "allergic cataracts," or, perhaps more correctly speaking, they should be called "cataracts associated with allergy."

ABSTRACT OF DISCUSSION

DR. ALAN C. WOODS, Baltimore. The cases presented by Dr. Daniel bring up in a somewhat different light the question of the relationship of the permeability of the lens capsule to cataract. While this syndrome of allergic cutaneous disorders with cataract has been reported previously, and three cases have been presented by Dr. Daniel, I myself have never seen patients with this particular syndrome. The report on these three patients is barren of laboratory investigations other than the evidence of skin hypersensitivity, and there is no positive evidence on which even a fragile theory may be based. Nevertheless, these cases are highly suggestive. Dr. Daniel's theory appears to be that a fine change in the function of the epithelial cells of the ciliary body in the content of the aqueous fluid or in the level of permeability and selectivity of the capsule of the lens can readily be reasoned to interfere with the efficient metabolism of the lens and its transparency, thereby producing a cataract in the otherwise normal individual. The first two suggestions are meaningless to me in relation to allergy. While it is quite possible that allergic reactions in the ectodermal tissues as a whole might readily produce changes in the ciliary epithelium and the contents of the aqueous, I am unaware of any evidence that such changes do occur, and I find it difficult to construct any theory explain-

ing cataracts on such speculative changes. As regards changes in the capsule of the lens, however, one may be more hopeful of building up some theory of causal relationship between the existing allergy and the cataracts. Primarily, the capsule of the lens has been shown to be impermeable to the globulin fraction of the serum or aqueous—the portion that probably contains antibodies. Even if one presupposes the presence of specific cytotoxins in the aqueous, there is no reason to believe that such cytotoxins could pass the capsule barrier and attack the lens substance. If one regards the situation somewhat differently and assumes that the capsule of the lens, an ectodermal structure, participates in the general cutaneous allergic reaction, it might readily follow that the permeability of the reacting capsule may be altered. Thus the capsule might become permeable to the normal aqueous and this aqueous filtering through the altered capsule might produce precipitation of the lens protein and cataract formation. Such a mechanism would really be that of a traumatic cataract, allergy to the lens capsule being the traumatizing factor. However, there are obvious difficulties to even such a theory. While it may reasonably be assumed that the capsule of the lens may participate in a general hypersensitivity of the ectodermal tissues to a specific allergin, it is difficult to explain how the intoxicating allergin obtains access to the capsule. Allergy is after all, the local reaction of sensitized tissues to the specific allergin and may be produced by any of the various methods which Dr. Daniel has enumerated. In this instance the most obvious explanation would be that the aqueous contains the specific allergin. It would be most interesting to obtain the aqueous from the eyes of the patients seen by Dr. Daniel and to use this aqueous in a skin test on the same patients.

DR. DERRICK T. VAIL, JR., Cincinnati. Dr. Daniel's paper appears to be the second discussion in the English language of a peculiar form of cataract (and one which appears to be pathognomonic) associated with atopic eczema or neurodermatitis. The first was by Dr. W. T. Davis in 1921. The disease association has been well established by several observers and I suppose, could be called a syndrome. In bringing this condition to notice it would have been better and less spectacular if Dr. Daniel had used the term "eczema cataract" or "neurodermatitis cataract," since the dermatologists themselves have not agreed entirely, as yet, on the allergic basis of eczema. The role of the endocrine glands has not been eliminated from the picture of neurodermatitis. Ollendorf and Levy found from an analysis of the literature that a disturbance of the endocrine glands was present in 20 per cent of the cases of neurodermatitis. They differentiate late exudative eczematoid, disseminate neurodermatitis or atopic dermatitis from contact dermatitis or eczema. Lowenstein, Kraus, Kurz, Bothmund, Andogsky and Vogt found definite endocrine disturbances in their cases of neurodermatitis and cataract. Dermatologists are at variance with one another regarding the allergic etiology of neurodermatitis. Taub and Zakon, for example, state that nearly all patients give a positive allergic history. On the other hand, Wise and Sultzberger while finding forty-two positive urticarial reactions in eighty-six cases, concluded that there are nevertheless grounds for doubting the importance of allergens for the etiology of neurodermatitis and of eczema in children. The definite thing known then, is that there is a rare, peculiar form of cataract associated with a skin disease called neurodermatitis. Therefore, in the present rather chaotic state of knowledge regarding neurodermatitis it seems best not to put the blame for the cataract on "overworked" allergy. Since neurodermatitis is such a complex disease, one could assume that the cataract was of metabolic origin because of endocrine dysfunction, or avitaminotic because of faulty absorption, or chemical because of blood calcium disturbance, as easily as of allergic origin. Finally, the enormous number of allergic people, especially the eczematous young adults may be considered and these few case reports of cataract compared with them. The "missing link" is still missing in this disease.

DR. W. R. BUFFINGTON, New Orleans. Delicate tissues are often profoundly influenced by all forms of intensive light therapy. During the past year I saw lenticular changes known as irradiating cataract in two cases result from intensive ultraviolet radiation given over a period of time for external ocular

lesions. One of the patients in Dr. Daniel's series—a Mr. F. A. R. of Baton Rouge, La., was examined by me in October 1934. This was some time before he came under Dr. Daniel's observation. His history shows that for at least two years previous to January 1934 he had suffered from a severe dermatitis, which affected the face and neck. The diagnosis was an allergic manifestation of unknown origin. The lesion had resisted all medication. Finally during the months of January and February 1934, the history continues, he was given intensive ultraviolet treatment about the face and neck, in the hope to relieve his discomfort. Although the disease had existed for a long time no disturbance of vision was ever experienced previous to this treatment. A few weeks subsequent thereto the patient's vision commenced to blur, so that by August 1934 it became necessary to dilate his pupils to improve vision in order that he might continue in his occupation. It was found that his poor vision was due to lenticular changes confined for the most part to the central area of the anterior capsule of each lens. Slit light examination showed them to be dense elevated opaque plaques, most likely a result of proliferating anterior epithelial cells. Careful observers have noted that this type of cataract often follows various forms of intensive light therapy, hence the term irradiation cataract. In this case the history and the observed facts cast a shadow of doubt on the theory that the lenticular changes are an allergic manifestation.

DR. C. ULYSSES MOORE, Portland, Ore. From 1918 to 1928, recurring attacks of corneal ulcers in my right eye were treated by some of the best known American ophthalmologists. Some searched diligently for syphilis and tuberculosis. Being disappointed there two recommended the removal of the offending eye. None of these learned men ever mentioned allergy as a possible cause of my trouble. An allergic minded pediatrician, however, solved the riddle through the making of scratch tests for some 200 foods. But for those tests I might now or soon be a candidate for a cataract operation, as my father was at 60. My family history shows none of the classic signs of allergy, such as asthma, hay fever, urticaria, eczema, headaches or colitis. But the food tests proved me mildly sensitive to more than a score of foods. I liked and still do tuna fish and beef steak, but a serving of either will make me prematurely tired and irritable. The following day I am likely to have a conjunctivitis. If I continue to eat offending foods for three days, a new corneal ulcer will probably develop. During the ten years from 1918 to 1928 more than 20 per cent of my time was lost because of an undiagnosed allergic eye. During the past seven years only a few days have been lost. These were primarily to demonstrate to doubting Thomases four different times that in my case tuna fish produces conjunctivitis, while halibut brings a speedy cure. If a committee of this group wishes to use me for additional clinical proof I shall, for the sake of other sufferers, consent.

DR. RUBY KATHRYN DANIEL, Rochester, Minn. I have tried to use terms as simple as possible because, in the study of the literature on allergy, many terms encountered are confusing, and some are used with a wide variety of meanings. I believe that this fact accounts for much conflict of opinion. One should appreciate fully and accurately the interpretation of such basic terms as allergy and immunity, these words cannot correctly be used interchangeably. This study does not propose to include laboratory work on the intra-ocular tissues of these allergic individuals; it is based on clinical deductions. However, laboratory animals have given evidence that the eye does participate in a general hypersensitivity. Burky observed that anaphylactic antibodies in the aqueous were increased apparently somewhat proportionally to the hypersensitivity of the skin in his allergic animals. Furthermore, one should not use the words atopic eczema and neurodermatitis interchangeably. For instance, in case 1 the first flare up at the age of 4, after handling a dyed Easter egg can be explained on a basis of atopic eczema, a reaction markedly allergic in nature, but this would not fall into the classification of neurodermatitis in the strict sense of the word. In this paper I simply intended to report the cases of three young adults who have marked allergic reactions, who further, have cataracts which seemingly have a significant onset and progress, and to suggest a possibility that in these patients these two may be related.

HYPERGLYCEMIA

EVALUATION IN THE TREATMENT OF DIABETES
MELLITUSHERMAN O. MOSENTHAL, M.D.
NEW YORK

The control of the blood sugar level in diabetes has been largely influenced by the impression that, since the so-called normal blood sugar concentration in healthy human beings is between 100 and 140 mg per hundred cubic centimeters, this is the optimal blood sugar level and should be striven for in the management of diabetes. The significance of hyperglycemia in the treatment of diabetes may be considered under four headings:

- 1 The renal threshold to dextrose
- 2 The normal blood sugar level
- 3 A high blood sugar level without glycosuria
- 4 A high blood sugar level with glycosuria

RENAL THRESHOLD TO DEXTROSE

The researches of A. N. Richards and his collaborators have established that urine originates by filtration from the blood through the glomerular membrane of the kidney, that this filtrate contains dextrose in the same concentration as the blood and that the dextrose in the glomerular filtrate is reabsorbed in the renal tubules, resulting in a bladder urine free from sugar in the clinical sense (fig. 1). When the blood sugar rises as high as 170 mg per hundred cubic centimeters, the dextrose is not all taken up in the tubules and glycosuria results (fig. 1).

Renal Glycosuria—The occurrence of glycosuria while the blood sugar concentration is normal—that is, 140 mg or less—is known as renal glycosuria. It is evident that this condition is not the same as diabetes, since in diabetes there is a diminished ability to utilize sugar within the body, while in renal glycosuria this does not hold true. The small amounts of sugar eliminated in the urine in renal glycosuria, even over a period of many years, do no harm and do not result in the complications seen in diabetes with the urinary excretion of large amounts of sugar. The importance of this fact will become clear further on when the control of hyperglycemia and glycosuria will be considered.

High Renal Threshold to Dextrose—The failure of sugar to appear in the urine when the blood sugar rises above 170 mg is regarded as due to a high renal threshold. This is mentioned here because in accounting for hyperglycemia in the absence of glycosuria it is frequently stated that this is an indication of decreased kidney permeability pointing to nephritis; this is incorrect, since a high renal threshold to dextrose is not due to diminished renal function but rather to hyperactivity on the part of the tubules. In fact there are many cases of acute and chronic nephritis in which there is renal glycosuria, that is, a lowered kidney threshold to dextrose, which might well be considered an impairment of tubular function.

NORMAL BLOOD SUGAR LEVEL

A normal blood sugar level is indicative of a perfect control in diabetes. If it is achieved by undernutrition, it is obvious that it is unwarranted. Malnutrition in diabetes may be justly regarded as one of the contribut-

ing causes for the development of diabetic arteriosclerosis and is a factor in the production of the complex syndrome of diabetic coma as shown by Peters, Kydd and Eisenman.¹

With the aid of insulin, malnutrition can readily be prevented but the possibility of partial starvation in diabetes is often overlooked both by the physician and by the patient, in an effort to avoid insulin, while conforming to the other standards of ideal therapy, that is, a normal blood sugar level and a urine free from sugar.

HIGH BLOOD SUGAR WITHOUT GLYCOSURIA

A high blood sugar without glycosuria is often observed in diabetic patients and others, especially in older persons. While sugar usually appears in the urine when the blood sugar reaches a level of 170 mg per hundred cubic centimeters, there are very many exceptions to this rule, blood sugars of 200 and 300 mg and sometimes higher are frequently found without demonstrable glycosuria. From what has been said in the section on renal threshold to dextrose, it is evident that the reason for this is not a lowering of the kidney's excretory power but an acceleration of the

Fig. 1—Renal threshold to dextrose. The production of renal glycosuria or a high renal threshold may be readily visualized from this diagram.

process of reabsorption from the glomerular filtrate by the tubular membranes.

Hyperglycemia, according to the available evidence, does not damage the tissues. In a study of the effect of changes in medium on lens epithelium cultures, Kirby, Estey and Wiener² noted no real difference in growth with dextrose concentration as high as 478 mg of dextrose per hundred cubic centimeters of medium, and it was only when the concentration was 578 mg that there was a slight inhibition of growth. Dr. Alexis Carrel³ fails to find any interference with tissue growth in mediums containing 300 mg of dextrose per hundred cubic centimeters and has not tried higher concentrations. Warren⁴ says "A high blood sugar level is not in itself injurious to the heart muscle."

In regard to the relation of bacterial growth to the concentration of sugar as it occurs in the blood of diabetic patients without complicating acidosis or glyco-

suria, all the observations point to the conclusion that concentrations of sugar in the hyperglycemic range do not favor bacterial growth. Hirsch-Kauffmann and Heimann-Trosien⁵ failed to demonstrate an acceleration of bacterial growth in the blood of diabetic patients containing as high as 410 mg of dextrose per hundred cubic centimeters, or when the blood sugar previous to the use of the blood as a culture medium was raised by infusion from 70 to 239 mg per hundred cubic centimeters, or when dextrose was added to normal blood, raising the sugar to 600 mg per hundred cubic centimeters, on the other hand, blood from children in diabetic coma did promote bacterial growth, but after recovery from coma the blood of these patients did not favor bacterial growth. Handsmann⁶ found that blood with dextrose concentration as high as 1 per cent was no better as a nutrient medium *in vitro* for staphylococci than normal blood, and also that the addition of dextrose to blood does not diminish its bactericidal power against the staphylococcus. In the preinsulin period some of us were systematically giving diabetic patients suffering with infections, usually skin abscesses or carbuncles, as much nourishment as possible, especially proteins, with the idea that, if the urine was sugar free and dehydration compensated for, the hyperglycemia was of no great importance, such diabetic patients recovered very well from their infections.

Hyperglycemia apparently furnishes a stimulus for the effective assimilation of sugar. Cori,⁷ in a review on carbohydrate metabolism, makes it clear that a high blood sugar promotes the formation of glycogen in the liver and he comments on the possible beneficial effects of a high blood sugar in diabetes as follows: "Lesser, puzzling over the fact that hypoglycemic symptoms appear at such a high blood sugar level in diabetic dogs, offered the interesting suggestion that in diabetes a high blood sugar level is necessary for any sugar to be utilized in the tissue."

Hyperglycemia is necessary for the utilization of dextrose in many diabetic patients. The conclusions of Soskin, Katz, Strouse and Rubinfeld⁸ are particularly interesting in this regard, as they showed that in elderly diabetic patients with cardiovascular disease the same symptoms that occur after insulin administration could be induced with a low carbohydrate diet. They found that serious cardiac manifestations such as paroxysmal auricular fibrillation, intraventricular block and angina pectoris, besides the usual symptoms of hypoglycemic shock, will in some persons follow the lowering of the blood sugar below their accustomed hyperglycemia to concentrations accepted as normal.

A high blood sugar is evidently necessary for an initiation of the processes of carbohydrate utilization in many individuals who do not have diabetes. This has been noted in the interpretation of sugar tolerance tests. The highest normal blood sugar that usually occurs after the taking of 100 Gm of dextrose is accepted as 160 mg per hundred cubic centimeters, there are many instances in which the only abnormality in the curve is the height to which it rises, frequently

above 200. These persons who exhibited "lag curves" or "high curves" subsequently did not develop diabetes.⁹

It is well known that in many nondiabetic patients, especially in elderly persons with arteriosclerosis and hypertensive disease, hyperglycemia is often found. Their sugar metabolism with the aid of a high blood sugar is normal and most of these persons do not develop diabetes in the clinical sense, although they have commonly been put in the vague, possibly unwarranted, classification of prediabetes. Here again is an example of the satisfactory utilization of sugar under the stimulus of hyperglycemia, which, in itself, produces no untoward effects.

In 1928 a report was made that an excess of sugar in the blood does not result in an increase of blood pressure in cases followed for a period of seven years.¹⁰ One of these patients is still under observation and has not developed hypertension or other complications characteristic of diabetes in the course of thirteen years, while a persistent hyperglycemia without more than transient glycosuria prevailed, as shown in the accompanying table. This man has a tendency to have hypoglycemic reactions at a high blood sugar level.

Relation Between Blood Sugar and Blood Pressure *

Year	Number of Blood Sugar Determinations			Blood Pressure Determinations			
	200 Mg or Over	150 to 200 Mg	Less Than 150 Mg	Lowest		Highest	
				Sys tole	Diast tole	Sys tole	Diast tole
1921			7	98	64	116	72
1922	10	5	11	92	58	114	78
1923	15	4	4	92	58	108	76
1924	8	4	4	82	53	110	66
1925	5	4	2	85	52	104	70

1928	8	0	0	97	61	128	84
1929	7	1	0	98	64	116	68
1930	5	0	0	90	64	128	60
1931	6	3	0	98	66	112	72
1932	4	2	1	94	65	128	78
1933	8	3	1	96	64	128	78
1934	2	4	2	102	66	122	64

* A man aged 61 has had diabetes mellitus since 1921 the disease being mild originally but now severe. A fairly constant hyperglycemia without more than transient glycosuria did not elevate the blood pressure or bring about other complications of diabetes in thirteen years. These blood sugar values are low for this patient since no determinations were made when the urine showed sugar.

The rapid circulation of the blood furnishes constantly repeated stimuli to all the agencies in the body capable of utilizing dextrose, and the advantages of hyperglycemia in promoting the storage and oxidation of dextrose thus becomes apparent. The carbohydrates are absorbed from the intestinal canal, enter the blood as monosaccharides, principally dextrose, and then the various tissues and organs are repeatedly influenced by the blood dextrose because of the rapidly recurring circulation (fig 2). The blood makes a complete circuit, being propelled from the heart and returning to the heart every three to five minutes, so that the opportunities for the normal disposal of dextrose when hyperglycemia exists are very great. The usual conception of carbohydrate metabolism disregards these multiple chances for the liver, voluntary and heart muscles, and other tissues to store and oxidize dextrose. The fact that this series of events does occur explains the transient character and harmlessness of hyperglycemia following on the ingestion of dextrose in some persons and also points to the benefits that may result from hyperglycemia in stimulating the utilization of dextrose.

HIGH BLOOD SUGAR WITH GLYCOSURIA

Small amounts of sugar may be constantly eliminated in the urine without any noticeable disturbance, as has been noted in cases of renal glycosuria, but a persistent glycosuria of sizable proportions representing a loss of 20 Gm or more of sugar in the urine per day entails a number of sequelae for which the body can compensate during a considerable period, but not indefinitely.

Weir Mitchell¹¹ made some interesting observations on this subject as long ago as 1860. He found that neither large doses of sugar administered to frogs, nor water deprivation alone, resulted in cataract, however, if the frogs were saturated with sugar and at the same time taken out of water, cataract developed within a few hours, but when the animals were again immersed in water, the cataract that had begun to form cleared up rapidly and completely. Transferring these observations to diabetes, it can be concluded that hyperglycemia without glycosuria is harmless but that hyperglycemia

Harrop and Schaub,¹² Lande,¹³ Atchley and his associates,¹⁴ Peters, Kydd and Eisenman,¹ and Himwich and his associates¹⁵) When these effects of sugar and water loss have become manifest, all these authors agree that the blood sugar may be reduced to normal and yet the condition may be far from controlled, thus indicating that blood sugar is not the pivotal point in the treatment of diabetes.

Moen and Reimann¹⁶ found that in "controlled" diabetes agglutinins for typhoid bacilli after vaccination developed as in normal persons, but in moderately controlled or uncontrolled diabetes the agglutinin response was weaker or poor. Philorhizin diabetes (in which there is only glycosuria and no hyperglycemia) in rats and mice diminishes their resistance to infection.¹⁷ These experiments indicate that loss of large amounts of sugar in the urine diminishes resistance to infection even in the absence of hyperglycemia. It is the opinion of Aschoff¹⁸ that arteriosclerosis is brought about by the dehydration of both intracellular and extracellular materials. Thus, whatever serious complication of diabetes is considered—malnutrition, acidosis, coma, liability to infections or arteriosclerosis—the cause for it does not appear to be hyperglycemia without glycosuria, but glycosuria and polyuria, that is, an extraordinary and long continued loss of sugar and water in the urine.

SUMMARY

1 High blood sugar in the absence of glycosuria is not due to diminished excretory activity of the kidney, nor is it significant of nephritis, but it is a harmless anomaly resulting from an unusually active reabsorption of sugar from the urine in the renal tubules.

2 While a normal blood sugar level and freedom from glycosuria are among the ideal objectives of therapy in diabetes, there are certain circumstances in which hyperglycemia and glycosuria should not be completely corrected.

(a) A normal blood sugar level and freedom from glycosuria should not be gained by underfeeding, since malnutrition favors the development of arteriosclerosis and is one of the contributory factors in producing diabetic coma.

(b) Small amounts of sugar may be eliminated in the urine without detrimental results, as shown in renal glycosuria. It is important to recognize this because, in cases of diabetes with a comparatively low renal threshold, there is with rigorous insulin control the possibility of repeated hypoglycemic reactions, which in all probability are injurious in both their immediate and their remote effects and, consequently, should be avoided even at the sacrifice of intermittent glycosuria.

(c) Hyperglycemia without glycosuria, according to the available evidence, not only has no damaging effect on the heart and other tissues but is a necessary stimulus for the proper assimilation and oxidation of dextrose in many persons, both diabetic and nondiabetic.

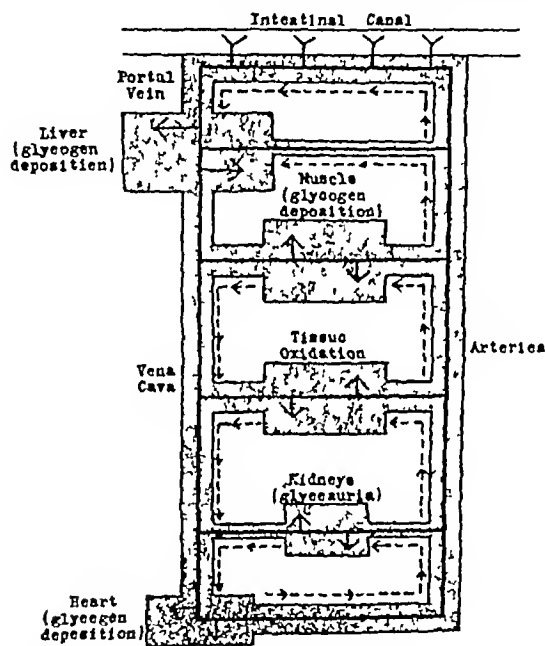

Fig. 2—The disposal of absorbed dextrose. It is desired to emphasize the fact that the various tissues and organs repeatedly exert their effect on the blood dextrose because of the rapidly recurring circulation.

associated with glycosuria, polyuria and dehydration is responsible for most of the serious complications in diabetes.

In our experience, diabetic arteriosclerosis resulting in gangrene and angina pectoris and cataract occur almost solely in those patients who have been extremely careless about their diet and insulin control for a period of five years or longer. Glycosuria and polyuria entail a most devastating series of events that cause untold damage—dehydration, desiccation of the tissues, hemoconcentration, undernutrition through loss of sugar in the beginning and subsequently through increased protein destruction and hypoproteinemia, acidosis, loss of electrolytes of the intracellular and extracellular fluids, diminished oxygen capacity of the blood, and decreased blood supply to the skin, heart and muscles. The idea that these changes, detected by painstaking laboratory determinations, are due entirely to polyuria and glycosuria and are not brought about by uncomplicated hyperglycemia alone, is generally acknowledged (Chang,

3 A prolonged, marked glycosuria with its attendant polyuria and dehydration is responsible for the diminished resistance to infectious processes, arteriosclerosis, formation of cataract, malnutrition, acidosis and coma, which are so characteristic of diabetes. Hyperglycemia without glycosuria is not a cause for these complications in diabetes.

889 Lexington Avenue

ABSTRACT OF DISCUSSION

DR ELLIOTT P JOSLIN, Boston. Hyperglycemia is a warning signal. Dr Mosenthal has distinguished between the cause of harmless and of harmful hyperglycemia. What puzzles me about the theoretical side of the question is that the diabetic patients who show hyperglycemia without glycosuria are old, have arteriosclerosis cannot see or have gangrene, and yet these are the very ones whose tubules are spry and functioning better than ever in their previous lives. It seems like an anachronism that the older the diabetic patient is, the better his tubules work. The charts that Dr Mosenthal showed present more blood sugars of 200 mg or more in 1922 and 1923 than in 1933 and still less in 1934. Dr Mosenthal is an exponent of sound treatment and this may be one of the reasons why his patient has done well. Faithful honest treatment in the course of time will lower many a queer high blood sugar.

DR EDWIN J KEPLER, Rochester, Minn. Should the medical practitioner be satisfied merely if diabetic patients do not excrete sugar in the urine, or should he demand further that the blood sugar be reduced to a level that approximates normal? At present there is no dogmatic answer to this question. The problem can be simplified if the objectives of treatment in diabetes are kept in mind. These objectives can be summarized briefly as follows: 1 The cardinal and incidental symptoms of diabetes should be controlled. This objective has been attained. 2 The development of degenerative lesions (chiefly arterial) incidental to diabetes should be prevented. Here the results obtained leave much to be desired. One of the chief reasons for failure lies in the fact that the cause of the high incidence of atherosclerosis in cases of diabetes is not known, and consequently to a certain extent treatment is on a theoretical basis. Various theories, incriminating a high level of the blood sugar, protein salt, calcium vitamins and, more recently, cholesterol have been propounded. These theories are reflected in the confusing multiplicity of diets that are advocated. Dr Mosenthal has presented additional evidence that the high level of blood sugar without glycosuria is not responsible for these arterial changes. In this respect I am in accord with him. It is useful for the purpose of treatment to classify cases of diabetes as: 1 Juvenile and adolescent, in these it probably would be beneficial to keep the blood sugar normal at all times; however, many of these are "brittle cases" and the blood sugar fluctuates violently and suddenly. 2 Early and adult, in which I prefer to keep the blood sugar normal, in a considerable number of these cases this can be done satisfactorily, and, if the blood sugar is normal one knows that the disease is being controlled. 3 Senile and senescent, in which I am satisfied to keep the urine free from sugar and let the blood sugar seek its own level. There are a number of plausible scientific reasons dealing chiefly with the behavior of the heart afflicted with coronary disease when the blood sugar is suddenly lowered to support this view. There is another less scientific reason however namely that elderly individuals do not tolerate sudden shifts in their intrinsic or extrinsic environment and many of them have become habituated to a high level of the blood sugar. If overenthusiastic attempts are made to lower the blood sugar to 'normal' by insulin or a too rigid diet, many of these patients are made miserable.

DR W S COLLENS, Brooklyn. The usual procedure in following the progress of a diabetic patient whether in practice or in recording in the literature, consists in the observation of the patient's urinary excretion of sugar in twenty-four hours and the determination of the fasting blood sugar. I should like to ask Dr Mosenthal whether he followed that procedure in his report and whether the blood sugars that he reported were obtained under fasting conditions. We carried out some

investigations at the Greenpoint Hospital to attempt a clinical interpretation of the fasting blood sugar. We performed twenty-one blood sugar studies on this patient over a thirty-hour period, at intervals varying between one and two hours. At 6 o'clock in the morning the patient's fasting blood sugar was 275 mg, at 7 o'clock it was 350. He then received his insulin and his breakfast, and for the next hour his blood sugar continued to rise to 400. At the end of an hour it proceeded to drop at a very rapid and precipitate rate of 17 mg per minute, so that by noon it reached 50 mg. He received his insulin and his lunch at 11:30. His blood sugar then continued at this level, and at 4:30 he received his insulin and his supper. At 10 o'clock at night his blood sugar was still under 100. At 3 o'clock in the morning it showed its first rise to 125 mg and from then on it continued to rise progressively, indicating that the insulin effect had worn off. The next morning he was not given any breakfast or any insulin, for we wished to determine the character of the fasting blood sugar at different hours of the morning. At 6 o'clock it was back to 340 at 8 to 375, at 10 to 415, and at 12 to 454. We repeated this experiment eight days later on the same patient, and instead of giving insulin and supper at 4:30 we gave them at 7. The result was that everything was delayed exactly two and a half hours, so that at 6 o'clock in the morning, instead of a blood sugar of 340 it was 110, and at 8, when it was 375 originally, he had 224. This does not mean that at the time the second experiment was performed his diabetes was less severe. It merely means that the recovery phase following the insulin effect was delayed because the insulin given with his supper was administered at a later hour. The fasting blood sugar depends first on the totality of the patient's diabetes, secondly on the amount of food that the patient receives in the previous meal, thirdly, on the amount of insulin he receives with the previous meal, and fourthly, on the time the intern gets up to take the blood. It simply means that the content of sugar in the blood is not a static phenomenon, that a patient receiving insulin as part of his treatment and adequately controlled possesses a normal blood sugar for more than eighteen hours of the twenty-four hour cycle, and that the blood sugar rises only in the early morning hours when there is no effect from insulin.

DR CHARLES T MAXWELL, Sioux City, Iowa. Hyperglycemia probably exists at times in all patients with diabetes of any severity. The normal individual weighing 150 pounds (68 Kg) with a blood sugar of 100 has approximately 5 Gm of sugar circulating in his total blood volume. With an increase of blood sugar to 140 he adds but 2 Gm to his total blood sugar. That is a pretty close regulation to ask the diabetic patient to follow. My interest is based on the care of patients and a number of years' personal experience as a diabetic patient. I believe that the blood sugar in younger individuals, who haven't become tolerant of high blood sugar, should be kept as near normal as possible. In all cases the sugar curve should be kept as regular and smooth as possible. The time element in the use of insulin is not sufficiently emphasized and it must be worked out in the individual patient. Insulin should be given long enough before food especially breakfast, to cause a falling sugar curve when the food is given. This will give a less pronounced rise after food a smoother curve throughout and less liability of an insulin reaction later in the day.

DR A A HEROLD, Shreveport, La. I would like to ask Dr Mosenthal two questions. First has he made the observation that the long-continued use of insulin seems to raise the renal threshold? It has been my experience that a patient who has been taking insulin for a long period of time has a higher blood sugar when he begins to show glycosuria than he had previous to using insulin. Second, has he ever observed symptoms of severe diabetes, including dehydration, in patients without glycosuria? I recall one patient who showed no glycosuria, with a blood sugar of more than 600 mg. In these extreme cases, I believe that more attention should be paid to the hyperglycemia.

DR HERMAN O MOSENTHAL, New York. The objectives in the treatment of diabetes are decidedly different now than they were some years ago. Beginning with the first day a patient with diabetes is seen, the aim is to prevent arteriosclerosis which through coronary disease, gangrene and cere-

bral accidents, is largely responsible for the present day diabetes mortality. This is the crucial problem in diabetes therapy at the moment. The maintenance of nutrition and the prevention of acidosis and coma, which loomed so ominously before the introduction of insulin, have been robbed of their threat, when diet and insulin are conscientiously and intelligently used. It is my contention that a blood sugar concentration above the accepted level of normal is not harmful, provided there is no glycosuria and dehydration. A high blood sugar will favor the assimilation and utilization of dextrose by the tissues and is not a factor in reducing the bodily resistance to infections or in promoting the development of arteriosclerosis. In many cases of diabetes, the burden and hazards of treatment are increased a great deal when a normal blood sugar level is insisted on. The case demonstrated, it is true, shows fewer blood sugar determinations above 200 in later years than at first, but it is obvious that the total number of blood sugar determinations has diminished since this patient has gained confidence and does not visit me as often now as formerly. The blood sugars in this patient are at low levels for him, since blood sugar determinations were made only on the days on which the urine specimens were sugar free when there is glycosuria, it may be taken for granted that the blood sugar is too high. Dr. Collens has called attention to the extreme variability of the blood sugar level. I have found this to be true. For many years I have taken the blood specimens for sugar determinations some hours after breakfast and after the first dose of insulin, believing that in specimens of blood taken at that time a more representative blood sugar value is obtained. In patients who are under insulin therapy the blood sugar is prone to be high before breakfast and in those who do not receive insulin the blood sugar is usually at its maximum two hours after breakfast or later in the day.

A STUDY OF ACTIVE IMMUNIZATION AGAINST SCARLET FEVER

IN CHARITABLE INSTITUTIONS AND PUBLIC
SCHOOLS OF PHILADELPHIA

J. NORMAN HENRY, M.D.
Director, Department of Public Health
PHILADELPHIA

This paper, as its title indicates, is an account of experiences of the Department of Public Health of Philadelphia with active immunization against scarlet fever. It is not in any sense a bacteriologic or biologic discussion of the specific nature of the streptococcus of scarlet fever or of the biology of the toxin. It is, however, a record of a sufficient number of cases to give weight to the conclusions that in this method of immunizing, as laid down by the Dicks, there is a sure means for the prevention of the disease and its after-effects.

It seems strange that reiteration of experience already so great and of figures should be necessary to convince the medical men at large of the efficacy of the proceeding, particularly in the light of their attitude toward diphtheria prevention in its struggle for general adoption. Almost ten years of accumulated facts was needed before final and complete acceptance was obtained, in spite of indisputable scientific proofs. Just so today is the same obstructive conservatism holding back the general adoption of scarlet fever prevention in private practice and public health work, at an enormous cost of suffering and death, not to mention the lesser question of cost in money and time.

The objectors bring up the threadbare question—again and again has it been answered—Does not the

toxin conquer only some symptoms of the disease, such as the rash, and thus make a more dangerous situation than was existent prior to its administration?

Another objection, and this a more real one, is on the ground of the reactions. The answer to the first question is emphatically no, if proper doses as laid down by the Dicks are used. The proof of the truth of the statement lies in the fact that there have been no cases of sickness in those who have been declared immune or who have been immunized which are in any degree suggestive of scarlet fever without rash or of any other group of symptoms or complications of the disease. The reactions are at times marked, but never sufficiently so as to have weight to overcome the value of the immunity conferred.

In Philadelphia we have been fortunate in having two experiences which we, at least, would not have sought voluntarily but which served as a valuable example to us in the very beginning of our work.

In 1926 scarlet fever immunization was introduced among the nurses and physicians at the Philadelphia Hospital for Contagious Diseases. Formerly there had been the usual heavy incidence of contagion common in such institutions. For several years after its introduction no case of scarlet fever developed in physicians or nurses fully immunized. When, however, in 1929 a former director of public health was persuaded to abandon the compulsory immunization, the disease again appeared in physicians and nurses, again to be eliminated ever since on the reintroduction (fourteen months later) of the use of the toxin. Twelve cases developed in the fourteen months of suspension of immunizations.

A second occurrence was an object lesson of equal or greater value to us, and again we were the innocent gainers in experience because of a situation that neither party concerned in would willingly have produced in the light of our convictions. Our work on any considerable scale began with the examination and immunization of children, nurses and attendants in a large private charity home and of a health center, under the jurisdiction of the Department of Public Health of Philadelphia, by Dr. Gladys Dick, who had kindly consented to inaugurate the work in Philadelphia.

In the case of the home, a year later a number of new children were admitted and scarlet fever broke out among them, but not one child (with one exception¹) or adult, declared immune or injected by Dr. Dick, took the disease, and the small epidemic was immediately arrested when the new children were tested and immunized. There was some misunderstanding that led to this interesting human experiment, the physician at the home and the department of public health were each awaiting a call from the other, which did not come until the fire alarm of scarlet fever.

The work of Dick testing and immunization against scarlet fever, as a public health measure, was begun in the latter part of 1932, and from that time until March 1, 1935, 10,057 children have been tested and those found susceptible treated. Of these, 4,053 were children living in institutions and 6,004 came from private homes. Most of the institutions seeking the treatment had recently experienced infection of scarlet fever, and the immunologists of the department of public health visited the homes and orphanages to make the test and administer the treatment at the request of the institution. Six thousand and four children came

from private homes and sought the treatment by the immunologists in the ten health centers conducted by the department of public health. Of these, 58 per cent were found positive and were immunized. Of the 4,053 children living in institutions, 1,052 (26 per cent) were found positive to the Dick test. The ages of the

children tested in institutions ranged from under 1 year to 16 years. This is a low percentage of susceptibility but is above that usually found in children who have lived in institutions for some years.

Table 1 shows, according to age, the percentage of positive reactions to the Dick test among children living in institutions and those outside.

REACTIONS AFTER ADMINISTRATION OF SCARLET FEVER TOXIN

Of the first 790 cases, 65.7 per cent showed no reactions to any of the injections of the toxin, 30.1 per cent showed slight reactions after one or another of the various doses. The reactions may occur after any one of the injections but were found most common after the third and fourth. Thirty-three cases (4.2 per

cent) showed marked reactions consisting of nausea, vomiting, fever, sometimes as high as 103 F, sometimes scarlatinal rash, sore throat, and pain in the joints and abdomen. Usually not all this rather formidable array of symptoms appeared in any one child, and it must be borne in mind that the toxin is a specific emetic and that the vomiting has less significance than if it were an evidence of systemic disturbance. The symptoms of reaction always appeared within six hours after the administration of the toxin and usually disappeared in a few hours. The most severe seldom were present for more than twenty-four hours. Causes other than toxin should be sought if illness is present for forty-eight hours or more after the treatment. Interestingly enough, the reactions were in these early cases less severe in the children in institutions than in those who were treated in health centers.

It was apparent that the after-care of the child is of great importance in modifying the severity of the reactions, and those who were given rest in bed and light diet after each treatment seldom had any but the mildest of reactions. Conversely, those who were allowed to exercise actively and to eat more or less heavy meals were more prone to marked reactions.

It is of importance in public health work to obtain the cooperation of the parent and clearly inform him

or her what to expect after any or all treatments, also, to instruct all concerned in the necessity of reasonable care of the child. In Philadelphia the department of public health issues a notice to the parent explaining the situation and emphasizing the need of after-care. Of course this is not necessary in private work, but at all times warning should be given of possibilities of unpleasant after-effects and particularly of the possibility of the appearance of a rash.

An analysis of our more recent 1,035 cases showed a much smaller percentage of reactions than was present in our earlier cases, and but 0.2 per cent were severe. Practically all of these cases were of school children, therefore ambulatory cases, and it is difficult to explain our favorable result unless it is that the instructions for after-care were given more attention than before. In the judgment of all concerned in the work in Phila-

* The positive case in the 5-6 year group was exposed to scarlet fever January 1935 but did not contract the disease.

delphia there is an overemphasis laid on the reactions. Local reactions were in no case severe, and no abscesses or ulceration occurred in any of the cases treated.

RESULTS OF RE-DICK TESTING AFTER FIVE DOSES OF SCARLET FEVER TOXIN

In a study of the first 790 cases found positive to the Dick test and subsequently treated with the scarlet fever toxin, 98.5 per cent showed negative reactions

to the Dick test after five consecutive injections of the scarlet fever toxin. In 1.25 per cent a sixth dose of the toxin was required before a negative reaction was obtained and only 0.25 per cent, or two cases, remained positive after a repetition of the fifth dose.

OCCURRENCE OF SCARLET FEVER AFTER A NEGATIVE DICK TEST

In a group of 159 cases treated in 1932, 1933 and 1934 and read negative to the Dick retest at that time, we found on retesting in March 1935 that only 3.1 per cent varied in reaction from the finding of a year or two before.

No case of scarlet fever has developed in any institution in which the patient was tested by one of the city immunologists.

In the 3,404 children treated in the health centers, scarlet fever developed in three cases after a series of doses of the scarlet fever toxin.

Two children, aged respectively 3 and 4 years, after five doses of the toxin were found positive on re-Dick testing, and when the fifth dose was repeated two weeks later a second retest gave negative results. In these children scarlet fever developed a year after the administration of the treatment. Whether the immunity wore off or the reading of the last re-Dick test was inaccurate is difficult to state.

10 to 11 years and over	20	20	50	50
1151, when children were Dick tested and readings were not made				

One child, aged 15 months, treated in 1933 with five doses of scarlet fever toxin, was re-Dick tested two weeks later, gave a negative reading and developed scarlet fever one year later.

In one patient with Little's disease, giving a negative reading (by Dr. Dick) on the primary Dick test in July 1932 and a history of having had scarlet fever, the second attack of scarlet fever developed in the fall of 1932. This child has been subjected to subsequent Dick testing and on each occasion has been negative to the test.

DURATION OF IMMUNITY

The experience in the Philadelphia work in respect to the duration of immunity as evidenced by the Dick test has been eminently satisfactory as far as our history goes.

Thus in a large orphanage, where the ages of the children ranged between 6 and 16 years, with the major portion in the older group, there were found early in 1933 only 9 per cent susceptible, as shown by the positive primary Dick test. Three months after the initial testing ninety of the group under 10 years of age, previously found negative to the test, were retested, and there was no variation from the original finding. In the fall of 1934, twenty of these children were again tested and there was no variation from the original finding.

In a foundling asylum where more than 400 children were Dick tested in 1933, eighty children in the 3 to 4 year age group in one dormitory showed a very low percentage of positive reactions after primary Dick testing. This group had recently received a third dose of toxin.

antitoxin for diphtheria immunization Six months after the initial test, the group showing negative reactions was retested and one child showed a very slight positive reaction

In the group re-Dick tested after treatment with the scarlet fever toxin in 1933, we found that 31 per cent showed a change from a negative to a positive reaction when re-Dick tested in March 1935

Table 2 surveys a group of children to whom the Dick test was primarily administered in 1932, 1933 or 1934 and found negative. These children were again tested in March 1935. In this group the change from a negative reaction to a primary Dick test in 1933 to a positive one in 1935 is 0.6 per cent.

Table 4 shows the results found in Dick testing 951 children in five public schools of the fortieth ward of the city of Philadelphia. The percentage of susceptibles in the different age groups ran very true to the accepted theory as to the susceptibility decreasing as the child grows older.

Our experience leads us to the following point of view. That the immunization against scarlet fever should be much more widely adopted and much more vigorously advocated by physicians than is done at present. That the proper administration and reading of the test most carefully within the specified time (from twenty to twenty-four hours) is fundamental. That the education of the parent is of importance in obtaining cooperation, and that the proper care of the child for a period of six hours after each injection will greatly lessen both the incidence and the severity of the reactions. That in my judgment the procedure should be adopted as a general measure alike in private practice and in public work. That scarlet fever can be eliminated as a serious private and public health problem.

Tables 5 and 6 show the detailed studies of re-Dick tests to determine changes of immunity over a period of three years, and a detailed analysis of the first 790 cases treated, and the last 1,035.

City Hall Square

ABSTRACT OF DISCUSSION

DR. JOHN A. TOOMEY, Cleveland. Between 1921 and 1926, sixty-six nurses contracted scarlet fever at a time when the nursing population was small and there were few affiliates. Between 1926 and 1935, 1,049 susceptible students have been protected. Eight developed scarlet fever, two after the first immunizing dose, both had positive Dick tests on admission to the hospital. One came down after the second dose, although she had a negative test on admission, five had the complete series of five doses, four having been immunized to a negative Dick test, and these four were still negative reactors when later admitted to the hospital with scarlet fever. One student received seven injections but remained a positive reactor and was still so when she developed scarlet fever two years later. I have seen eight nurses who contracted scarlet fever in other hospitals. Two of these had two doses of toxin, one still had a positive test when she developed the disease, and the other was not tested. Six had had the complete series of five doses of toxin, four had been immunized to a negative Dick test and were negative reactors when they later contracted scarlet fever, one had been still positive after immunization and on later admission to the hospital. Discounting the incomplete immunizations, I had five failures of protection among my students, although four were immunized to a negative Dick test. One should not feel too bad about the failure of complete immunization in these few nurses. There are always immunization failures with any procedure. Even an attack of the natural disease does not immunize any better.

A committee of the American Academy of Pediatrics in a recent report to the members on the subject of active immunization in scarlet fever adopted the conservative attitude Dr. Henry speaks of. It did not condemn the use of scarlet fever toxin or deny its efficacy but felt that the reactions were severe enough to prevent general adoption of the procedure. Perhaps the use of a toxoid would help in avoiding these unpleasant reactions. Few nurses have not had some reaction from a local inflammatory response, minor in character and such as is seen with any immunizing procedure to the individual presenting all the signs of scarlet fever. Occasionally the reactions were so severe that I have had to stop the program of immunization, particularly in cases in which swollen joints developed. The type of scarlet fever present in the United States will have to be more severe for me to agree with Dr. Henry that this program should be made a public health measure. How long do these injections immunize the individual? Dr. Henry's observation extends in some instances to about three years. Our own nurses are protected for at least three years. I feel that this question will have to be answered before active immunization can be pushed as a public health measure.

DR. PASCAL F. LUCCHESI, Philadelphia. I am especially interested in the 6,004 children who were recruited from private

homes, because they represent the average strata of life in the districts in which they reside and are therefore the type of patients with which the family physician is familiar. Of these children, 3,304 were found susceptible and were given weekly injections of scarlet fever toxin. The majority of them required five doses, but a sixth dose was necessary for a few. The faithfulness with which the parents brought their children to the nearby health centers week after week for these inoculations is the best recommendation that can be accorded this treatment, it is reasonable to assume that parents would not allow their children to return for injections if any serious reactions had been experienced. The much feared severe reactions were not experienced in this study. The reactions are in proportion to the cooperation between the physician and the parents, and also to the knowledge of the physician on this subject. This is demonstrated by the small number of severe reactions experienced by the department of public health in their study. In a group of 790 children, 301 per cent had very mild reactions and 4.2 per cent severe reactions, while in a group of 1,035 only 0.2 per cent had severe reactions. At the Philadelphia Hospital for Contagious Diseases this method of prevention has been in use since 1926. Up till now, 695 doctors and nurses have been given the Dick test, of whom 185, or 26.6 per cent, were found susceptible and immunized. No serious reactions have been experienced. The production of immunity by this method of prevention is even more startling. As high as from 98.5 to 99.6 per cent were immunized with five and six injections respectively. In one institution where I myself immunized twenty-nine children ranging in age from 18 months to 12 years a 100 per cent immunity was produced. An objection sometimes raised with reference to this method of immunization against scarlet fever as a public health measure is the length of time required for the completion of the treatment. The treatment can be completed in most cases in about six weeks, which includes the re-Dick test. However, when a sixth injection is required, in the event of a positive re-Dick test, eight weeks would be necessary. If one compares this with immunization against diphtheria, either by the injection of toxin-antitoxin or the one or two dose toxoid it will be found that from six weeks to six months or longer may be required for the completion of the treatment, whereas in this form of treatment against scarlet fever within six or eight weeks one will know very definitely whether a patient has acquired immunity. The favorable response of Philadelphia parents to this treatment is most encouraging.

DR. THEODORE MELNICK, Philadelphia. It is a matter for regret that physicians in certain vicinities have been reluctant in accepting this preventive measure. This hesitancy can be attributed to the fact that the persons receiving the immunizing treatment may often experience after one or more of the toxin injections some unpleasant reactions such as headache, fever, nausea, vomiting, abdominal pain, scarlatiniform rashes and sore throat. While these reactions in themselves are not dangerous to life, they are of sufficient moment to make the clinician reluctant to use the toxin and more often cause the parents to refuse further treatment. Because of similar experiences, a series of experiments were undertaken with the hope of eliminating as much as possible both the severity and duration of the reactions. The following procedure was decided on: 1. A mild laxative the night before the day of the injection. 2. Restriction of food on the day of the injection both before and after the injection. 3. Restriction of activities after the injection. 4. Injection during the latter part of the day so that the individual will retire soon after the treatment. Drs. Dick, Kiefer, Smythe and Nesbit, Rhoades, Lees and today Drs. Henry and Toomey have reported reactions in from 10 to 30 per cent of individuals after receiving this immunizing treatment, which reactions lasted from twenty-four to forty-eight hours. Following the procedure I have just outlined, the reactions were milder and did not last as long as those reported by others. Only 4 per cent of individuals reacted, and fourteen hours later, or the morning following the injection, 98 per cent of those injected were up and about attending to their usual activities. Sore throat or eruptions were never encountered. As to the efficacy of this preparation, the value of scarlet fever immunization in the personnel of the contagious

disease hospitals has already been mentioned. My experience, both in private practice and otherwise, has been very encouraging. In one orphanage in which the children attended public schools in the neighborhood, not one case of scarlet fever has appeared since immunization three years ago, whereas, prior to this, cases cropped up every year. In another very large orphanage, no cases of scarlet fever appeared for two years after immunization. One case did appear in an inmate, recently admitted, who had never been Dick tested or immunized. No children in contact with the patient developed the disease. Scarlet fever immunization is advocated, but measures to lessen reactions should be instituted until the toxin preparation is improved so that it will not cause any reactions.

DR. J. NORMAN HENRY, Philadelphia. I have been interested in Dr. Toomey's remarks, with which, incidentally, I do not agree. The object of my paper is to prove from actual experience that immunization against scarlet fever by the method described should be introduced generally as a public health measure. Because of this, I spoke in the rather strong way I did concerning obstructive conservatism. I submit that, when one has had a rather large experience for more than three years and a smaller one going back to 1926 with the results described in the paper, it is but natural that one should be convinced. Particularly is the experience in the Philadelphia Hospital for Contagious Diseases convincing when the compulsory immunization was stopped twelve cases of scarlet fever developed in fourteen months in nurses and interns, and no case has occurred since its reintroduction. If for three years we are able to immunize children of preschool and school age and if it is granted that the immunization will hold in most cases for several years longer, then we are performing a big public health measure. We are tiding these children over the susceptible period. I consider it an insistent public health measure.

TREATMENT, MODIFICATION AND PREVENTION OF MEASLES BY USE OF IMMUNE GLOBULIN (HUMAN)

IRVING M. LEVITAS, MD
WESTWOOD, N. J.

The use of Immune Globulin (Human) in the modification of measles has been known for a considerable period. McKhann and Chu¹ gave doses of from 5 to 6 cc to forty-two children who were exposed to the disease. Of this number, thirty-seven were completely protected and in five mild modified measles developed. Whether the child was protected or modified measles developed depended on the number of days of incubation that had elapsed prior to injection of the extract. These cases were all in an institution. There has been little in the literature concerning the treatment of fully developed measles through the use of Immune Globulin (Human). It is part of my purpose in this paper to show the very definite therapeutic value of Immune Globulin (Human) in treatment of well developed cases of measles.

MODE OF PREPARATION AND STANDARDIZATION OF IMMUNE GLOBULIN (HUMAN)

The preparation used in these cases was Lederle's product known as Immune Globulin (Human). It is prepared and standardized in the following manner. Under the regulation of the National Institute, placentas are selected from healthy white women with negative Wassermann and Kahn tests. The cord blood must show a negative Wassermann reaction on test. The

placentas are ground in a meat chopper and extracted with saline solution. The saline extract, free from tissue and blood cells, is mixed with ammonium sulphate in half saturated solution, which precipitates the globulins that contain the protective antibodies. This precipitate is collected and dissolved in water, and the salts are removed by dialysis. The final filtrate is concentrated so that it contains about 12 mg of protein nitrogen per cubic centimeter. The final fluid, containing phenol as a preservative, is filtered for sterilization through a Berkefeld filter and represents the product known as Immune Globulin (Human).²

IMMUNE GLOBULIN (HUMAN) IN THE ACTUAL TREATMENT OF MEASLES

There are in this series twenty-eight cases of measles treated with Immune Globulin (Human). As they were all in private practice, and not just an experimental group, only about one fourth of the total number of patients who were observed during the epidemic of December 1934 to April 1935 were given the extract. The cases were selected mainly for two conditions: (1) cough and (2) toxicity. The first symptom was one that was easy to evaluate as to intensity, while the second presented a difficult problem as to measurement. It was in the cases of a severe, dry, irritating, racking cough that the results were very satisfactory. The dose was arbitrarily placed at from 1 to 2 cc. Of the twenty-eight cases treated, twenty-five responded favorably. Three cases showed no particular effect, but the extract in these cases was given at an earlier time than in those in which relief was gained through its use. All injections were given intramuscularly in the buttocks.

CASE 2—A girl, aged 6 years, with an oral temperature of 104 F and a rash present on the face, had been coughing incessantly for twenty-four hours and had been unable to sleep because of it. The cough was unproductive, brassy and very racking. One cubic centimeter of the preparation was given about 2 p. m. During the evening the mother noticed that the temperature was high, but the cough became easier and less frequent. The next morning the rash was out fully and the temperature was normal. The cough had changed in character to a slight, nonirritating, loose cough and was not especially frequent.

CASE 7—A boy, aged 12 years, when first seen had a rash on the face and an oral temperature of 104 F. The child was very miserable, mainly because of the severe, dry, hacking cough. The mother stated that he had been coughing almost incessantly for the past four days and had had but little sleep. The patient complained of soreness of the abdominal muscles as a result of it. One cubic centimeter of the preparation was given. That evening, about three hours following its use, the mother stated that the temperature seemed very high but that the cough subsided and the patient slept the whole night. The next morning the temperature was 102 F., the rash was out heavily on the body, but the cough was loose and nonirritating and the child was comfortable. The following day the temperature was normal.

CASE 20—A girl aged 6 years, when seen in the afternoon, had a rash on the face and body, and the oral temperature was 103 F. The child had a dry irritating, hacking cough and had slept poorly for the past three nights. One cubic centimeter of the preparation was given. Five hours later the temperature was 104.5 orally. This was easily controlled with acetylsalicylic acid, 5 grains (0.3 Gm.). The child slept the entire night with the exception of occasional requests for a drink of water. The next day the cough was loose and nonirritating, the patient was comfortable in spite of a fever of 102.5 F. The appetite was fair and she was much less toxic. The following day the temperature was normal.

CASE 21—A boy, aged 9 years, had a rash on the face and an oral temperature of 103 F. There was a severe, dry cough

² Coca, A. F. Personal communication to the author.

that had been present for three days. I had seen the patient the day before, but the mother had refused to allow the use of the preparation. However, she called the next day because the child was still coughing severely, and as a result he had not slept during the night and he had vomited frequently as well. Cough syrups were of no avail. Two cubic centimeters of the preparation was given and five hours later the temperature was 105 F orally. This was easily controlled with acetylsalicylic acid and an alcohol sponge. The cough had already decreased and the child was more comfortable. The next day the cough had almost ceased and the mother expressed the wish that she had permitted its use earlier.

CASE 5—A boy, aged 8 years, had a rash on the face and a very severe cough. Two cubic centimeters of the extract was given and the next day the cough had practically ceased. This case was especially interesting because the patient had been brought to my office the night before with the complaint of having had a dry, hacking cough for three days. The child had an oral temperature of 101 F, and there was considerable nasal and pharyngeal congestion. No Koplik spots were noted and, as it was early in the epidemic, measles was not suspected. A tentative diagnosis of acute sinusitis was made and treatment given accordingly. The next day the mother called and stated that a slight measles-like eruption had appeared on the face, the cough was still bad, and the child had hardly slept during the night. Two cubic centimeters of the preparation gave relief from the cough in three or four hours.

CASE 25—A boy, aged 9 years, had been sick for about eight days with what appeared to be a scarlet fever-like eruption. This case was probably one of dual infection. *Streptococcus haemolyticus* was obtained in cultures from the throat. For the last four days he had been very toxic and there was a scarlatiniform eruption on the body and arms. Angina was not severe. A severe dry cough then developed, which was unresponsive to all types of medication, including cough syrups and throat lozenges. Koplik spots were then noted and the next day a typical measles rash appeared on the face. In view of these facts, the dual nature of the infection was taken into consideration and 2 cc of Immune Globulin (Human) was given. The cough turned within a few hours to a tolerable one and solved a very difficult problem. The next day the rash progressed, and the patient had a typical measles course superimposed on the streptococcal infection.

There were three cases in which no particular benefit was observed. These patients were all given 2 cc of the preparation on the first day of the prodromal symptoms. There was only a slight temperature rise, and respiratory symptoms were practically nil. They continued on their regular course apparently unaffected. It is probable that there are few or no immune bodies during the early course of the disease and that the anti-

it was not possible to do so satisfactorily. However, there were no reactions that gave any undue alarm, and the temperature when too high was easily controlled with antipyretics and sponging, after which there was no return to the high point. It was only in those cases in which the mothers used thermometers frequently that any mention was made to the physician of hyperpyrexia. It is better from a practical standpoint not to have the mothers take the temperatures, as they do not notice any great change if they do not do so. The highest febrile point usually occurred from four

TABLE 2—Results of Inoculation After Intimate and Moderate Contact

Day of Exposure When Injected	Degree of Contact	Number of Cases	Results
1 2	Intimate	13	Modified measles
1 2	Moderate	2	Complete protection

to five hours following the administration of the immunizing agent.

Local Reactions—About two hours following the injection a local soreness began, which was characterized by tenderness to touch and spasticity of the muscles over the site of the injection. No local treatment was needed, and after twenty-four hours no complaints were heard from this source. Mothers were advised as to what to expect and further warned against making an important issue out of this, as none of the children complained more than a short time.

Allergic Phenomena—No allergic manifestations were noticed following the use of the preparation.

Summary—1 Immune Globulin (Human) was used in the treatment of twenty-eight cases of measles in which the disease had reached the prodromal stage or the rash had appeared.

2 Results in twenty-five cases were excellent.

3 The cough was markedly influenced through the use of this agent.

4 Febrile reactions were moderate and easily controlled.

5 Local reactions were not marked, and no allergic phenomena were observed.

USE OF IMMUNE GLOBULIN (HUMAN) TO MODIFY MEASLES

There is a very definite difference between the procedure in the hospital and that in private practice in the problem of measles prevention and modification. In institutions it is more practical to attempt to stop disease because of the required quarantine and the possibility of spread to other patients and nurses. In private practice, when the children are at home, it is better to modify all cases when the children are in a good state of health. If this is done the patients will develop active immunity and therefore have protection against future attacks, whereas if the disease is prevented entirely they would probably at some later date contract measles. The reason for this is that Immune Globulin (Human) merely confers a passive immunity for from a few weeks to months. If a preventive dose is given, the next time the child has been exposed to the disease the physician may not be called until the patient has reached the stage at which it is impossible to modify the attack. The great majority of calls to patients, especially at the beginning of an epidemic, are either late in the prodromal symptoms or at the time the eruption has appeared.

TABLE 1—Results with Immune Globulin (Human) in Eighteen Cases

Developed mild modified measles	13
Uninfluenced developed regular measles	3
Completely protected	2

bodies given at this stage through the use of this agent are not sufficient to influence the symptoms. Later in the course of the disease, at the end of the prodromal symptoms, enough immune reaction has occurred so that, with the added benefit of Immune Globulin (Human), enough antibodies are present to aid in the subsidence of symptoms. In this series of cases doses of from 1 to 2 cc were used, and it is probable that larger doses given at this stage would help materially.

Febrile Reaction in Treatment—The febrile reaction following the use of the preparation in treatment usually reached a peak of from 104 to 105 F rectally. This was not accurately measured, since in private cases

In the present group, eighteen patients were given a dose of the immunizing agent in order to modify the course of the disease. The results are given in table 1.

Dosage—In all cases the dose was 2 cc except in the case of one infant, aged 11 months, in which 1 cc was given with satisfactory result.

Time of Injection—Fifteen patients were given the injection from one to two days following exposure. All cases were successfully modified with the exception of two, in which the disease did not develop at all. The extract was given at a time, except for the latter two cases, when another child was being treated in the same house for measles, and on the first visit the unaffected person was injected. The two patients in whom measles did not develop had had a moderate amount of contact through playing outdoors with a child who subsequently developed measles, but the exposure was not as severe as with those who lived intimately in the same house with a measles patient. Table 2 gives the results in those who were inoculated from one to two days following exposure.

There were three cases in which 2 cc of extract was injected five days after exposure, and in these the results were unsatisfactory, as the course in all three was the usual, typical measles course. Another factor was that all three of these patients were in the same family and lived in cramped quarters. Karelitz and Schick³ have shown that the degree of exposure decid-

TABLE 3—Result in Late Inoculation

Day of Exposure When Injected	Degree of Contact	Number of Cases	Results
5	Severe	3*	Usual measles course

* All cases in the same family.

edly influenced the amount of immune serum needed to gain modification. Apparently in these three cases the overwhelming amount of exposure, along with the fact that the injection was given late in the incubation period, contributed to the poor results. Therefore it is logical to conclude that under similar circumstances a larger dose of the preparation would be needed to acquire modification of the disease (table 3).

All thirteen cases that were successfully modified had the same characteristics. These are:

1 **Incubation Period**—This averaged about thirteen days, which was slightly longer than in the uninoculated, which ranged from about ten to eleven days. The reason for this is that the first sign of measles in these cases was the rash, and there were no prodromal symptoms as in the unprotected, shown in the accompanying chart.

2 **Prodromal Symptoms**—These were practically nonexistent. A few cases showed a slight catarrhal condition and occasionally slight headache. The first sign of the disease in practically all cases was a slight rash, usually accompanied by a mild febrile reaction. In many cases the child was apparently normal in the morning, and the mother would suddenly notice the rash in the afternoon. This would be the first indication of the illness.

3 **Rash**—The rash in all but two infants, aged 11 and 14 months was slightly less than in the unmodified case. In these infants the rash was very mild, macules were widely scattered and the color was light rose. In the older children the rash was somewhat less than

in the unmodified and did not appear in the same sequence. It was generalized almost immediately and reached its height by the second day from the time of appearance instead of the third or fourth day, as in those who did not receive the extract.

4 **Febrile Course**—In the modified cases the course of the fever averaged two days and with the uninoculated patients it was approximately from four to seven

TABLE 4—The Febrile Reaction in Thirteen Cases

Patient*	Age	Days of Fever	Highest Fever		
			First Day	Second Day	Third Day
1	11 months	2	102.5	100.3	Normal
2	21 months	2	103.4	104.6	Normal
3	14 months	3	102.0	101.0	100.0
4	5 years	2	102.3	101.0	Normal
5	7 years	2	102.0	101.0	Normal
6	2½ years	2	102.0	101.3	Normal
7	5 years	1	104.0	Normal	Normal
8	5 years	1	103.0	Normal	Normal
9	5 years	2	101.0	103.0	Normal
10	2 years	2	101.0	101.0	Normal
11	2 years	2	101.0	101.0	Normal
12	3 years	2	101.0	103.0	Normal
13	6 years	2	100.2	101.5	Normal

* Patients 7 and 8 and patients 10 and 11 are similar twins. All temperatures recorded were rectal.

days. The highest temperature in this modified group was 104.6 F by rectum. In no case was it necessary to give antipyretics or sponging because of fever. Table 4 shows the highest febrile reaction for each day in the thirteen cases.

5 **Coryzal Symptoms**—Coryzal symptoms were all mild with varying intensity in each case. The cough, which in this epidemic was particularly distressing, was in these cases nonirritating and loose and did not require medication. Conjunctival and nasal symptoms were inconsequential.

6 **Toxicity**—There was practically no degree of toxicity. All the children were lively and difficult to keep in bed or at rest, and their appetites were good throughout, in fact, they were no more uncomfortable than they would have been with an infection of the upper respiratory tract of mild intensity.

7 **Allergic Phenomena**—There was no evidence of any allergic manifestations at any time.

8 **Complications**—In case 2 left otitis media developed three days following a normal temperature. The

Course of disease after exposure in unmodified and modified cases

measles course had been very mild. In case 12 slight cervical adenitis developed on the left side, with which there was no febrile reaction.

9 **Febrile Reaction Following Injection**—A series of twelve patients under observation in a hospital ward were given 2 cc of Immune Globulin (Human). Temperatures taken every four hours rectally showed an average maximum temperature rise to 103 F, which took place about six hours after injection. Therefore, on the average, the febrile reaction occurred on the day of injection and was gone the next morning. There was a moderate degree of malaise, anorexia and occa-

sionally slight nausea. These symptoms disappeared with the subsidence of fever.

10 Local Reaction—There was considerable soreness the first day at the site of injection. By the next day it had decreased and was not a factor for complaint, the children being up and playing about without any especial discomfort. At present, considerable work is being done to attempt to alleviate both the local and the febrile reactions. However, in doses of from 1 to 2 cc. the reaction was hardly more than annoying, and as long as the parents were advised of it beforehand there was no undue alarm on their part.

Summary—1 Injections of 2 cc caused modified measles in thirteen out of eighteen cases.

2 Three cases were not successful and ran the usual measles course, as in these the inoculation was made the fifth day following exposure and the contact was extremely severe.

3 Two cases were completely protected by 2 cc of extract. Exposure was only moderate.

4 In all patients who lived in the same household with another child who had measles, the disease subsequently developed.

5 All symptoms were extremely mild in the modified cases.

USE OF IMMUNE GLOBULIN (HUMAN) FOR PREVENTION OF MEASLES

There were twelve patients in the ward of Hackensack Hospital when a case of measles broke out in a child after having been in the ward for two days. Each child was given 3 cc of Immune Globulin (Human) to prevent the disease. No children came down with measles. The intimacy of contact was the usual ward type, as none of the children were ambulatory. The nearest bed to the affected child was about 3 feet distant. It is logical to assume that the three or four children nearest the infected child would be most likely to develop the disease, and the ones farthest away would not be as likely to do so. Because of this factor, reports of protection of numbers of children in hospitals are not reliable, as the degree of contact is at times very slight and children far removed from the sick child are probably not exposed. More reliable work of this type can be done in homes, where the actual contact is definite and intimate. The value of complete protection in the hospital wards is great, and here Immune Globulin (Human) may be advantageously used. As 2 cc causes modified measles, the dose for protection is probably from 3 to 4 cc, depending on the degree of contact and the age of the child.

Summary—1 Twelve cases exposed to measles in a hospital ward were totally protected through the use of 3 cc of Immune Globulin (Human).

2 More exact work of this type is possible in the home than in institutions, because in the latter only a few children near the patient are probably exposed. Therefore, case reports of large numbers protected in institutions are probably unreliable.

CONCLUSIONS

1 Immune Globulin (Human) is of definite value in treatment, modification and protection against measles.

2 It is easily given, the stock is standard, and the dose is small.

3 It is of especial value in young infants, in whom the disease carries high morbidity and mortality.

UVEOPAROTITIS

SAMUEL J. COHEN, M.D.

AND

MEYER A. RABINOWITZ, M.D.

BROOKLYN

We have reviewed the recorded cases of the combination of uveitis and parotitis, either with or without the presence of nerve palsies or skin eruptions, and have found that about sixty-five such cases have been reported. Five such reports appeared in the American literature and the rest were described in the journals of foreign countries, particularly the Scandinavian. The rarity of the subject justifies the report of an additional case as well as the attempt to describe and discuss briefly the course and manifestations of such an entity. We have noted also that the majority of these cases have been reported by ophthalmologists in their special journals, but, since this type of case is often encountered by the internist, a discussion of the syndrome from the medical clinician's point of view is warranted.

REPORT OF CASE

A Jewish housewife, aged 34, was referred to the medical ward of the hospital by the ophthalmologist Dr. Isaac D. Kruskal, Jan. 31, 1934. Three months prior to admission she came to the outpatient clinic because of tiredness, nervousness, pains in the legs and weakness of about one year's duration. Two or three months before, "blotches" appeared on both lower extremities. At that time both lower extremities were found to be covered with a rash, which was blotchy, reticulated, red and slightly elevated, but not tender or painful. Early in December 1933 the rash started to fade. In November 1933 she had a sensation of having "gray threads" before the eyes, misty vision, difficulty in discerning distant objects and swelling of the upper eyelids. Soon the left side of the face swelled and in a few days similar swelling of the other side of the face developed. These swellings began to subside about the middle of December.

As a child the patient had whooping cough, chickenpox and measles. She was always subject to head colds, lacrimation and sneezing and for the past fifteen years had taken rhinitis tablets. Her habits were normal. She had never had a chronic cough, hemoptysis or night sweats. The family history was devoid of any taint of chronic or infectious ailments, except that her mother was suffering from diabetes and a sister was subject to repeated attacks of urticaria. The patient married at the age of 23 and had two healthy children. Her husband was well.

On examination it was noted that she was well developed but slightly pale. The eyelids were somewhat reddened and swollen. The pupils reacted very sluggishly. There was a faint ciliary injection, many spots were noted on the posterior surface of the corneas, the vitreous was hazy. Both parotid glands were enlarged and small shotty lumps could be felt therein. In the right supraclavicular region, near the median insertion of the sternocleidomastoid muscle, there was a gland the size of a hazelnut, not adherent and not tender. The heart and lungs showed no gross abnormalities. The spleen was felt just below the costal margin. Over the anterior aspects of the arms and legs there was noted a fading blotchy erythema not tender or elevated.

The urine examination showed no abnormal elements. The fasting blood sugar value was 120 mg. per hundred cubic centimeters and following a dextrose tolerance test of 100 Gm. the value rose to 230 mg. at the end of one-half hour, 188 mg. at the end of one hour and 145 mg. at the end of two hours. The urine contained sugar in the half-hour and the hour specimens. Examination of the blood showed hemoglobin, 75 per cent (Dare), erythrocytes, 4,200,000, leukocytes, 7,100, polymorphonuclears, 67 per cent, lymphocytes, 24 per cent, eosinophils, 6 per cent, and basophils, 3 per cent. The sedimentation rate of the erythrocytes was ninety minutes for 18 mm. The Was

From the medical service of Dr. Meyer A. Rabinowitz, Jewish Hospital.

Sermann and Kahn reactions of the blood were negative. The tuberculin intradermal skin reaction was negative with 0.1 and 5 mg. A roentgenogram of the chest showed tumefaction of the nodes at both lung roots. The pulmonary structure itself was clear except for an area of productive pleuritis on the right side, where there was an annular shadow opposite the level of the third rib anteriorly. The interpretation of the roentgenologist (Dr M. G. Wasch) read as follows: "I do not believe an active pulmonary Koch process is present, the condition impresses me as most likely that of a lymphoid tumefaction."

The gland from the right supraclavicular area was excised, and on section it showed a homogeneous grayish appearance with a smooth firm surface. Microscopically it showed the lymph follicles to have been replaced by large masses of epithelioid tissue, there remaining but a narrow rim of lymphocytes. Many of these tubercles contained horseshoe giant cells. Tubercle bacilli were not found.

The temperature ranged between 99.2 and 100.8 F. After a stay of three weeks in the hospital there was no appreciable improvement in any of the signs or symptoms, and the patient was discharged.

Heerfordt¹ is to be credited with the recognition and the naming of the syndrome, although such cases were described prior to his publication. Subsequent writers have attempted to augment or change the nomenclature by attaching to it an anatomic or an etiologic term, but since the causative agent is as yet not established beyond a doubt, we suggest that the original nomenclature be used until the real etiologic agent is discovered. This illness affects females more frequently than males and is more commonly encountered in the third decade, but children and older adults are not exempt.

Signs and Symptoms.—Preceding the appearance of the signs and symptoms which typify this disease, the patient often experiences dryness of the mouth, malaise, lassitude, drowsiness, weakness, night sweats, anorexia, nausea and vomiting. Of course, such prodromal symptoms do not characterize this syndrome alone, as they often precede many other ailments. Such symptoms may last several weeks or months before the systems characterizing this syndrome become involved. There is a lack of regularity in the order of the appearance of the signs and symptoms which go to make up this disease entity, not all the systems are necessarily always involved. The facial palsy, neuritis and the skin rash are not found in every case, but the parotitis and uveitis are encountered in all the instances and therefore characterize this syndrome.

Parotid Involvement. The parotid glands are usually the first to become involved. At first one gland swells, and this is soon followed by a swelling of the opposite gland. Both parotid glands are always affected. We take exception to the statement of Garland and Thomson² that in two of the recorded cases there was unilateral enlargement, Müller's³ case and the case of Critchley and Phillips.⁴ The former case can hardly be placed in the category of this syndrome, and in the latter case the patient did in fact present a bilateral parotid swelling. The parotid gland is hard, not painful or tender, shotty and not adherent. It never suppurates, although the swelling may last several months

or years before it subsides. Long after the disappearance of any visible swelling, small shotty-like nodules persist for a long time.

Lymphoid Tissue Involvement. The submaxillary, cervical, sublingual and very often the supraclavicular glands are found to be enlarged but not tender. They do not suppurate but ultimately resolve.

Ocular Involvement. Without exception the eyes are always involved in this disease, although in the majority of cases this follows the parotid involvement. Here, too, one eye is involved first, but both are ultimately affected. The patient at first complains of misty vision, as if specks of dust or threads were in front of the eyes. Pain in the eyeballs is an early symptom, and there is an inability to discern distant objects. The pupils become irregular and dilated and often do not react to light. Keratitis, ciliary congestion and nodules in the iris appear, and the vitreous shows opacities. Synechiae, optic neuritis and atrophy often result in permanent visual defects even though some of the other eye signs may subside. The palpebral fissures are narrowed and pseudoptosis may be present.

Nerve Involvement. Facial palsies are the most common nerve disturbances encountered, and they are found in about one third of the cases reported, in less than half of them it is bilateral. One side of the face is involved at a time, as the affected side subsides, the opposite side becomes paralyzed. The palsy may precede, follow or appear simultaneously with the swelling of the parotid glands. It usually lasts several weeks but may endure as long as a year. It subsides, leaving no trace of muscle weakness. Occasionally the paralysis will recur. Milder involvements of the nervous system, such as polyneuritis, paresthesias, intercostal neuralgias, ptosis of the lids, dysphagia and paralysis of the soft palate and vocal cords, are occasionally seen.

Skin Involvement. A rash may appear on the anterior surface of the body, arms or legs before or during systemic involvement. It is an erythema resembling a toxic erythema or an erythema nodosum, flat or slightly elevated. It is not painful to touch, does not itch and lasts but a few weeks.

Fever. The temperature may or may not be elevated and when it is, there is only a low fever. In some cases it may reach 103 F. The fever may also continue throughout the course of the illness, but it does not cause the patient any great degree of discomfort.

Laboratory Data.—The urine shows no abnormality. A slight anemia may be present, though it is not characteristic of this disease. An eosinophilia of from 3 to 20 per cent is usually found, but the total number of leukocytes is not necessarily increased or diminished. The bacteriologic examination of the parotid secretion and the conjunctiva shows no specific organism, but the usual flora. The histopathology of this disease is as yet not definite, because too few biopsy examinations of the involved tissues have been made. There were three deaths in this series and they were due to miliary tuberculosis. The excised lymph glands showed epithelioid and giant cells, but no caseation or tubercle bacilli. The lacrimal gland tissue resembled a lymphoma. The parotid gland showed no tubercle bacilli, giant cells or caseation. Further and more detailed studies are necessary to establish the specific tissue reaction of this disease as well as the identity of its exciting agent.

Etiology.—There are many controversial opinions regarding the etiology of uveoparotitis. Some authors state that the syndrome is produced by the tubercle

1. Heerfordt, C. F. Ueber eine 'Febris Uveoparotidea subchronica an der Glandula parotis und der Uvea des Auges lokalisiert und häufig mit Parösen cerebraspinaler Nerven kompliziert', *Arch. f. Ophth.* 70: 254, 1909.

2. Garland, H. G., and Thomson, J. G. Uveoparotid Tuberculosis. *Quart. J. Med.* 2:157 (April) 1933.

3. Müller, M. Bemerkungen zu der Arbeit von H. Rieth über Indozyklitis bei Parotitis epidemica und anderen Speicheldrüsenschwellungen und über ihre Beziehungen zur Tuberkulose, *Klin. Monatsbl. f. Augenhe.* 64:387, 1920.

4. Critchley, M., and Phillips, P. A Case of Uveoparotitic Paralysis. *Lancet* 2:906 (Nov. 1) 1924.

bacillus Thus, in one of Bang's⁵ cases, the case of Souter⁶ and the case of Garland and Thomson² miliary tuberculosis was found at postmortem examination Uhthoff⁷ felt that his patient's ailment was due to tuberculosis because he found positive physical signs at the left apex of the lung Lehmann⁸ reviewed twelve cases of uveoparotitis and in only three cases did she find signs suggestive of tuberculosis Gjessing⁹ thought that this disease is a peculiar reaction form of tuberculosis Schall¹⁰ maintained that the etiology is tuberculous, basing his opinion on the fact that his patient recovered following tuberculin therapy, but his patient showed no evidence of a tuberculous infection anywhere Reimers¹¹ reasoned likewise and Roenne¹² stated that the etiology is undoubtedly tuberculous Cavara¹³ concluded that the disease is a special form of tuberculosis, although inoculations of parotid tissue into the rabbit and guinea-pig were negative to tuberculosis Reimers¹¹ examined the parotid gland in his case and it showed no giant cells or caseation Lehmann's⁸ patient showed epithelioid and giant cells but no caseation or tubercle bacilli Weve¹⁴ injected parotid gland tissue from his patient into the anterior chamber of the rabbit's eye, but the microscopic examination showed no evidence of tuberculosis Van der Hoeve discussed Weve's paper and expressed the belief that the disease might be due to a healed form of tuberculosis One year later Weve¹⁵ expressed the opinion that this might be a form of paratuberculosis Tanner and McCurry¹⁶ recently reported three cases of uveoparotitis, one patient had suffered from pulmonary tuberculosis, but the two others were completely free from such an infection Leeksa¹⁷ felt that this disease is but a complication of mumps, although Heerfordt¹ and McKaig and Woltman¹⁸ showed the lack of a relationship between the two Hamburger and Schaffer¹⁹ thought that this is a variety of the Mikulicz syndrome Mackay²⁰ felt that this is an infection secondary to a mouth infection MacBride²¹ was of the opinion that the nature of this disease is toxic or toxin-infective Parker²² considered this to be an infective multiple

neuritis Ramsay²³ considered it to be a form of deficiency disease Altland,²⁴ however, believed that the etiology is as yet unknown

Prognosis—While the mortality is low, there being recorded but three deaths, the morbidity is high The involvement of the uveal tract often results in permanent visual defects The other systems involved clear up completely

Treatment—Many methods of treatment have been employed, the results being as good with one form as they are with another The tuberculin treatment is particularly advocated by the ophthalmologist Cutler²⁵ used inorganic arsenic, Jackson,²⁶ Lerner²⁷ and Hamburger and Schaffer¹⁹ used radiotherapy, and Ramsay²³ administered thyroid extract It is apparent that there is no specific form of treatment, and since the greater number of cases cleared up, it is reasonable to assume that this disease is self limited Treatment should therefore be directed toward maintaining the nutrition and resistance of the patient General hygienic measures are in order Foreign protein therapy, we believe, is indicated

COMMENT

That this syndrome constitutes a well defined clinical entity is now beyond any doubt, its etiology, however, is still in controversy The promulgators of the tuberculosis theory failed to supply sufficient solid proof to justify their conclusions It is true that pulmonary tuberculosis was found in one case and miliary tuberculosis in three others, yet in the majority of the recorded cases no indisputable clinical or pathologic evidences of tuberculosis were shown A diagnosis of uveal tuberculosis requires proof of the presence of a primary focus,²⁸ yet no such positive proof is available Tubercle formation with a central giant cell and surrounding mononuclear phagocytes is a tissue reaction that can be caused by organisms other than the tubercle bacillus The tuberculous patient is tuberculin sensitive except under conditions of massive tuberculous infection, but it must be conceded that the patients in this series had no massive infection, if at all infected, it was mildly, and yet the tuberculin reactions were negative in the majority of instances, in the cases in which the tubercle bacillus was demonstrated, the reaction was positive. Furthermore, microscopic evidence of tuberculosis in either a biopsy or an animal inoculation was never proved This condition is also readily differentiated from mumps not alone because of the chronicity of the former and the acute course of the latter, but because this disease occurred in persons who had had mumps before It is difficult to conceive that this entity even resembles the Mikulicz syndrome or that it is a deficiency disease, but we are confronted with the frequent finding of eosinophilia and a skin rash, which are likely to be evidences of an allergic state This allergic state is not caused by the tubercle bacillus, because the tuberculin reactions in these cases were negative Therefore,

it is quite likely that this syndrome is produced by an organism as yet not isolated, which produces a low grade infection in a sensitized individual and runs a slow course with a spontaneous termination

SUMMARY AND CONCLUSION

- 1 No definite etiologic factor appears to be responsible for uveoparotitis and its syndrome
 - 2 Further search for the causative agent or agents is necessary
 - 3 The disease is chronic and self limiting
 - 4 The only permanent morbidity of this illness is visual impairment
 - 5 Since this disease is chronic and possibly infectious, foreign protein therapy is suggested

THE SIGNIFICANCE OF PYURIA IN CHILDREN

ALEXANDER B HEPLER, MD

SEATTLE
AND

RUSSELL T SCOTT, MD
LEWISTON, IDAHO

Within recent years there has been a growing recognition of the importance of a complete urologic examination in infants and children when there is presumptive evidence of urinary tract disease. This increasing application of modern diagnostic methods to urologic conditions in children has established a number of facts, the most important of which are that (1) congenital narrowings of the caliber of the urinary tract, chiefly at the points of normal anatomic narrowing, are very common, and congenital obstruction is an important factor in urinary diseases both in children and in adults, (2) chronic infections are usually secondary to or are perpetuated by these obstructions, and a chronic or recurrent pyuria almost invariably indicates some anatomic defect, and (3) urinary tract diseases in children are often obscured by symptoms pointing to other conditions, frequently gastro-intestinal, and the examiner must be on the alert for presumptive evidence of urinary disease or it will be missed.

Infants and children do not localize their subjective symptoms, and many of the lesions are "silent," in that they do not give symptoms. Attention is usually called to the urinary tract by the presence of pus in the urine. Pyuria is the most important sign of urogenital disease in children.

The question then arises: What constitutes a pyuria of clinical importance and what is its significance when it is encountered in an ordinary routine examination? These questions are instigated by the fact that there is a tendency among pediatricians to evaluate its importance on the quantitative basis and to conclude that a few pus cells are normal or indicate contamination and that a large amount points to infection of the urinary tract.

One frequently hears the remark that there is a small amount of pus in the urine but not enough to mean anything. The general standard of a normal limit seems to be from 6 to 8 pus cells per high dry field. No qualifications are made as to the method of collection or examination. Since pus cells are never a normal constituent of the urine, it is to be inferred that

pus in this amount is taken to be contamination and if over this to indicate disease. The fallacy of such an assumption is obvious.

However, a review of the literature gives the same impression. Eisendrath¹ says that "one finds five to seven leukocytes to the high dry field in the urine of normal children." The method of examination is not mentioned or the basis for this conclusion. Jarrell,² in an article on pyelitis in infancy, says that, "if there are as many as ten leukocytes to the field, a diagnosis of pyelitis may be made." The method of collection or examination is not mentioned. Smith³ concludes that the diagnosis of pyuria is justified only when the number of white blood corpuscles is considerable, at least 8 to 10 per high dry field, but does not say whether in the catheterized or voided specimen, nor does he give any reason for this arbitrary limit of 10 cells. Ramsey⁴ gives as a standard to warrant a diagnosis of pyelitis or pyelocystitis "colon bacilli in numbers and pus cells to exceed ten to the field" in the catheterized, uncentrifuged specimen. Helmholtz⁵ feels that the presence of a small amount of pus in the urine has been overemphasized in the diagnosis of pyelitis. He gives as a normal "in the uncentrifuged urine from boys obtained with ordinary precaution, two or three pus cells per low power field, and in the urine from girls, not more than six or eight cells." He does not state the basis for these figures.

METHOD OF EXAMINATION

There has been no systematic study reported either to confirm or to refute these assumptions. To find out whether there was any basis for them and to throw some light on this subject, we studied all the patients admitted to the Children's Orthopedic Hospital for a period of nine months, March 1931 to January 1932, in the manner outlined in table 1.

On admission, a voided specimen of urine centrifuged and uncentrifuged was examined. If there was pus in any amount the patient was catheterized, and centrifuged and uncentrifuged specimens were examined. If pus was found, the patient's history was checked carefully for urinary symptoms, a plain roentgenogram taken, a combined phenolsulphonthalein function determined and a complete cystoscopic examination done, including pyelo-ureterograms or excretory urograms. Even though no pus was found in the catheterized specimen, the patient's history was carefully checked for urinary symptoms either past or present, and if positive the child was observed or a complete renal study made. This was not done with the idea of establishing or recommending a routine method of examination but simply to find out what pyuria in children means under all conditions.

VARIATIONS IN THE VOIDED AND THE CATHETERIZED SPECIMENS

In this manner the urines of 694 children (400 males, 294 females) were examined during the nine months from March 1931 to January 1932. The oldest child was 16 years of age and the youngest 24 hours, with an average age incidence of 7.2 years. Pus was found in the voided centrifuged specimens of 687 children, or 99 per cent, in the amounts noted in table 2, in the

4 Ramsey W R Acute Infections of the Urinary Tract in Infants and Children Subsidizing Without the Appearance of Pus in the Urine Am J Dis Child 24:218 (Aug.) 1922

5 Helmholtz, H F Journal Lancet 50:131 (March 15) 1930

voided uncentrifugated in 246, or 36 per cent, in the catheterized centrifugated in ninety-nine, or 13 per cent, and in the catheterized uncentrifugated in sixty-four, or 9 per cent

It is obvious from this that the term pyuria may vary considerably in its meaning if it is used in the sense of pus in the urine in any amount, regardless of the method of obtaining and examining the specimen

TABLE 1—Method of Examination

While there were 687 children with pus in the voided urine, only ninety-nine had it in the catheterized specimen. Therefore, catheterization is imperative in urinary diagnosis in children. Contamination is possible in males as well as in females (400 of the group were boys). Even if the glans and prepuce are cleansed, there may be contamination from a low grade urethritis secondary to a previous balanitis. A two glass test would eliminate this, but it is a simple matter to pass a small catheter.

So many variable factors are introduced by centrifugation, such as time and rate of spinning and method of collecting the sediment, that it is of no value in a quantitative estimation of pus.

TABLE 2—Quantitative Estimation of Pus Cells in the Urine of Six Hundred and Ninety-Four Children*

	Voided		Catheterized	
	Centrifugated	Uncentrifugated	Centrifugated	Uncentrifugated
Occasional (less than 1 per high dry field)	272	148	34	27
1 to 5 per high dry field	324	73	29	18
5 to 10 per high dry field	52	12	11	10
10 to 20 per high dry field	26	10	8	7
Over 20 per high dry field	13	3	7	2
Totals	687	246	89	64
	(90%)	(30%)	(18%)	(9%)

* These included 400 boys and 294 girls (oldest 16 years, youngest 24 hours, with an average age of 7.2 years) who were admitted to the Children's Orthopedic Hospital during a period of nine months from March 1, 1931, to Jan. 1, 1932.

INCIDENCE OF URINARY TRACT DISEASE IN THE PRESENCE OF PYURIA

Following the plan of examination outlined, we found that a complete renal study was indicated in sixty-six cases. Of these, sixty-four children had pus in the catheterized uncentrifugated urine and two had none, but the histories in the latter were suggestive. Of these sixty-six children, twenty-six had demonstrable urinary tract disease, as shown in table 3.

From this it is obvious that the amount of pus in a urine properly collected is no indication either of the

kind or of the severity of urinary tract disease. There were three patients with advanced infected hydronephrosis with less than 1 pus cell per high dry field, and in one with an osteovesical fistula from sclerosing osteomyelitis of the ilium there was a rare pus cell, while in another with a similar condition there were many pus cells. Fifty per cent of the twenty-six children with demonstrable urinary tract disease had pus in the urine in amounts well under what is quoted in the literature as a normal pus content.

Forty of the sixty-four patients (table 4) with pus in the catheterized uncentrifugated specimen had no demonstrable urinary tract disease, but most of them had some active extra-urinary infection. In only six of the forty was the count over 5 cells per high dry field, and three of these had acute appendicitis and two

TABLE 3—Incidence of Urinary Tract Disease in Sixty-Four Children with Pus in the Catheterized Specimen

Children with Pus in the Catheterized Specimen Uncentrifugated	Number of Pus Cells per High Dry Field	Children with Demonstrable Urinary Tract Disease	Diagnosis
	0	2	1 neuromuscular dysfunction of the bladder (encephalitis) 1 hydronephrosis
27	Occasional (less than 1)	4	1 unilateral hydronephrosis 1 bilateral hydronephrosis 1 suppurative bhp disease with sinus to the bladder 1 urethral cysts
18	1 to 5	7	2 neuromuscular dysfunction of the bladder (spina bifida) 1 hydronephrosis 1 acute pyelonephritis 1 urethrotigonitis (chronic mastoiditis) 1 congenital stricture of external meatus 1 metastatic abscess of kidney with perinephric extension
10	5 to 10	4	1 acute pyelonephritis 1 chronic pyelonephritis (tuberculous spine) 1 hydronephrosis 1 congenital valves of posterior urethra (double kidney)
7	10 to 20	7	5 acute pyelonephritis 1 neuromuscular dysfunction of the bladder (spina bifida) 1 congenital cysts of posterior urethra
2	Over 20	2	1 congenital strictures ureterovesical junctions (bilateral pyonephrosis) 1 suppurative bhp disease with sinus into the bladder
Total 64		26	

severe mastoiditis. It might be contended that these should be included in the cases of pyelonephritis, but the clinical evidences of pyelonephritis were absent, such as lumbar tenderness, fever and dysuria. The pyuria rapidly cleared up with the subsidence of the primary infection.

There were forty-one patients with bone or joint tuberculosis and, realizing the possible association of renal tuberculosis with these lesions, we observed them carefully during the period of this study. In none of the forty-one were we able to demonstrate tubercle bacilli after careful examination on various occasions. Only seven had pus in the urine and in none of these was there demonstrable evidence of urinary tract disease.

A large number of these children were treated by prolonged immobilization on frames and in casts. This study does not confirm the generally accepted opinion that prolonged immobilization tends to urinary stasis, infection and stone formation.

It is evident that, of sixty-four children with pus in the catheterized urine, only 37 per cent had demonstrable urinary tract disease. It might be contended that the others were unnecessarily subjected to a complete renal study. However, it is also evident from the observations recorded in table 3 that the number of pus cells is no indication either of the kind or of the degree of urinary tract disease. The necessity for a complete study is not determined by a quantitative estimation of pus. It is undoubtedly "a greater error to miss making an early diagnosis through neglect of a proper examination than to mistake the indications and unnecessarily subject the child to examination."

It must be remembered that the study included all children in the hospital during the comparatively short period of nine months. Of the twenty-six with demonstrable urinary tract disease only ten were admitted for diagnosis and treatment of a urologic condition, and

TABLE 4—Pyuria (Catheterized Uncentrifugated) in Forty Children with no Demonstrable Urinary Tract Disease

Number of Pus Cells per High Dry Field	Number of Cases	Diagnosis
Occasional (less than 1)	23	4 tuberculosis spondylitis* 4 no diagnosis 3 osteomyelitis 2 tuberculous hip disease* 2 congenital dislocation of hip 2 scoliosis 1 congenital syphilis 1 fracture 1 appendiceal abscess 1 mastoiditis 1 mitral disease 1 infantile paralysis
1 to 5	11	2 scoliosis 2 Perthes disease 1 osteomyelitis 1 strabismus 1 encephalitis 1 genu varum 1 tuberculosis spondylitis* 1 congenital dislocation of hip 1 cleft palate
5 to 10	6	3 acute appendicitis 2 mastoiditis 1 congenital dislocation of hip
Total	40	

* In the forty-one cases of bone or joint tuberculosis in this series, the urine was examined very carefully for tubercle bacilli three different times with negative results. In seven there was pyuria (see above) but none presented any urinary symptoms nor any demonstrable urinary tract disease.

only nine had subjective symptoms directly referable to the urinary tract.

BACTERIA

The necessity for negative cultures as a criterion of cure in urinary infections in children has been emphasized by Helmholz. A study was made of the comparative value of fresh smears and cultures in determining the type of infection. One hundred and eighty-three catheterized urines were examined both by smear and by culture (table 6). Positive smears were obtained in fifty-five and positive cultures in sixty-two. There were four positive smears with negative cultures and nine positive cultures with negative smears, a total difference of thirteen. Thus, in 183 examinations the smear and culture agreed in 170, or 92 per cent. The stained smear is as valuable as the culture in routine examinations of the urine and should be used as a routine. Of the sixty-two positive cultures, there were found staphylococci alone in twenty-seven, staphylococci and B. coli in seventeen, B. coli alone in thirteen, staphylococci and streptococci in two, B. subtilis in two, staphylococci, streptococci and B. coli in one.

SUMMARY AND CONCLUSIONS

There is a tendency among pediatricians to evaluate the importance of pyuria in children on a quantitative basis and to assume that a few pus cells are normal or indicate contamination and that a large number point to urinary tract infection or disease.

Various arbitrary limits of normal are given without qualification as to the method of collection or exami-

TABLE 5—Subjective Symptoms Directly Referable to the Urinary Tract

None had subjective symptoms referable to the urinary tract

nation. No systematic study of a large number of children has been reported that would definitely confirm or refute many of the assumptions that appear in the literature on this subject.

To this end 694 infants and children were examined during a period of nine months in the Children's Orthopedic Hospital, from which study we conclude that:

1 Catheterization is imperative in urinary diagnosis in children. Ninety-nine per cent of 692 children had pus in the voided urine and only 13 per cent in the catheterized.

2 The amount of pus in a urine properly collected is no indication either of the kind or of the severity of urinary tract disease. In the twenty-four children in this group with demonstrable urinary tract disease, exactly similar lesions existed with pus counts that varied from less than 1 per high dry field to more than 20 per high dry field. Fifty per cent of the children with demonstrable urinary tract disease and a number with advanced lesions and severe infections had

pus in amounts well under what is frequently set forth as a normal count.

3 If a persistent or recurrent pyuria, no matter what the cell count, is taken as a criterion for a complete renal study, a number of children will be subjected to what is apparently an unnecessary examination, for only 37 per cent of the sixty-four with pus in the catheterized specimen had demonstrable urinary tract disease. However, as can be noted in table 3, the amount of pus is no guide as to the necessity for cystoscopy. Many of the obstructive lesions are

"silent" and a few pus cells the only indication of a pathologic process, so that it is undoubtedly a "greater error to miss making an early diagnosis through neglect of proper examination than to mistake the indication and subject the child to what is apparently an unnecessary examination"

4 Many urologic lesions in children are "silent" or have misleading symptoms. Only nine of the twenty-six children in the study who were found to have urinary tract disease had subjective symptoms that were in any way referable to the urinary tract. In only ten was there any presumption of a urinary lesion. The remaining sixteen were discovered through the routine study of pyuria.

5 Urinary complications in children with bone and joint tuberculosis are not common, and prolonged immobilization on frames or in casts does not tend to urinary stasis, infection and stone formation. Forty-one of the children examined had bone or joint tuberculosis. In none were tubercle bacilli found in the urine after repeated and careful examination. Only seven had pus in the urine, and none of these had any demonstrable urinary tract disease.

6 In determining the type of organisms in 183 urines, the fresh smear and cultures agreed in 170, or 92 per cent.

THE ANTIDOTAL ACTION OF POTASSIUM PERMANGANATE

ROBERT A. HATCHER, M.D.
NEW YORK

Potassium permanganate was recommended as an antidote for certain poisons by Moor,¹ whose papers embrace a curious mixture of truth and error. Potassium permanganate is commonly recommended as an antidote for organic poisons in the stomach, but there is a striking divergence of opinion concerning the amount to be administered and the concentration of the solution to be used. One hesitates to cite the names of persons with reference to a common error, but a few concrete examples are desirable. Fantus² says

The nearly always fatal dose of barbitol is about 10 Gm., of phenobarbital about 4 Gm. and of dial about 24 Gm. The stomach should be washed thoroughly with diluted (pink) permanganate solution.

The color of solutions of potassium permanganate varies from lilac to deep purple, depending on the volume and the concentration, and whether viewed by transmitted or reflected light. A physician was once asked to select from among several flasks the one that contained the solution corresponding to the description "pink" just mentioned. The concentration of the solution he selected was 1 1,000,000, and the flask contained a total of 1 mg. in 1,000 cc. of water. Potassium permanganate does not destroy barbitol, and, if it were active, 1 mg. would not oxidize more than 3 mg., less than a thirtieth of 1 per cent of a fatal dose of barbitol.

From the Department of Pharmacology, Cornell University Medical College.

With the technical assistance of Miss Josephine St. Mary and Miss Jeanne Ossent.

1 Moor, W. O. *Potassium Permanganate as an Antidote for Morphine*. M. Rec. 45:200 1894. *The New Antidote for Opium Poisoning*, Brit. M. J. 1:1369 1895. *Ueber die Behandlung der akuten Opium- und Morphinumvergiftungen mit Kaliumpermanganat*, Therap. Monatsheft 17:562 1903.
2 Fantus, Bernard. *Therapy of Barbiturate Poisoning*. J. A. M. A. 103:749 (Sept. 8) 1934.

In contrast with that useless dose, dangerous amounts are sometimes recommended. Sydney Smith³ said

Hydrocyanic Acid. Potassium permanganate has been shown to inhibit the action of the poison and half a liter of 3 to 5 per cent solution should be immediately administered.

The larger dose (25 Gm.) of potassium permanganate recommended by Smith (500 cc. of a 5 per cent solution) is about 25,000 times as much as that recommended by Fantus for washing the stomach in a case of barbitol poisoning. Smith⁴ says

In strong solution or in the solid state it acts as a corrosive or strong irritant, while after absorption it appears to cause paralysis of the heart. In one case about half an ounce caused death in five hours with corrosion of the mouth and pharynx. In small doses, such as 3 grains (0.2 Gm.), alarming symptoms of gastric irritation and collapse have been caused.

According to Smith, death has resulted from a little more than half of the dose that he recommended in hydrocyanic acid poisoning, and alarming symptoms of gastric irritation and collapse have resulted from less than a hundredth part of that dose. DeBusscher⁵ found that an oral dose of only 100 mg. of potassium permanganate per kilogram sometimes proved fatal in dogs. This corresponds to about 6.5 Gm. (100 grains) for man, or about one fourth of the dose recommended by Smith.

Moor observed that potassium permanganate destroys an equal weight of morphine instantly, even in the presence of blood. In fact, he maintained that with blood or egg albumin it forms a compound which destroys morphine even more actively than does potassium permanganate itself. He injected morphine sulphate intravenously into a rabbit, causing a slowing of the respiration, he then injected subcutaneously into another rabbit a similar amount of morphine sulphate, followed by intravenous injections of potassium permanganate and failed to observe any essential change in the respiration. He concluded that potassium permanganate is capable of destroying morphine in the circulation.

Moor failed to understand the difference between the effects of an intravenous and a subcutaneous injection of a given dose of morphine and the reaction that occurs in the blood. It is true that potassium permanganate destroys morphine in the blood in vitro, but morphine leaves the circulation rapidly and is fixed in the tissues, and there is no evidence that the subcutaneous injection of potassium permanganate causes the destruction of poison in the circulating blood. Moor stated correctly, however, that potassium permanganate decomposes protein slowly and that it is useful for the destruction of those poisons which it decomposes rapidly in the stomach—not for those which it decomposes more slowly than it does protein.

It is beyond the scope of this paper to give details concerning the use of potassium permanganate under varying conditions, but the following factors have been considered with reference to several poisons:

- 1 The rate of decomposition in acid, neutral and alkaline solutions.
- 2 The amount of potassium permanganate required to decompose a given weight of a substance, and conversely, the

total amount of potassium permanganate that is decomposed by a given weight of a substance.

3 The effective concentration of the reagent.

4 The influence of protein, caffeine and tannin (tea and coffee) on the rate of destruction of poisons

Potassium permanganate in tenth-normal (3.1606 Gm to the liter) or hundredth-normal solution was used in nearly all the quantitative experiments. The disappearance of purple was the end-point for the determination of the reduction of potassium permanganate. This was fairly sharp in those experiments in which there was little interference by the color of the products of decomposition, but it was unsatisfactory in those in which turbid mixtures resulted. Some of the experiments were performed at room temperature (about 25 C, or 77 F) some at body temperature (about 37 C, or 98.6 F), but the rate of reaction was essentially the same.

When an excess of potassium permanganate was added to an alkaloid, the products of decomposition sometimes continued to reduce the potassium permanganate at a much slower rate, and the weight of potassium permanganate reduced was six times that of the alkaloid in some cases.

The rate of destruction of each of several alkaloids and the approximate amount of potassium permanganate required to destroy a given amount were determined by adding measured amounts of a solution of potassium permanganate to a solution of the poison, and after intervals varying from two minutes to half an hour extracting any undecomposed alkaloid by shaking the solution with chloroform after the addition of sodium bicarbonate, distilling the chloroform and testing the residue by means of Valser's reagent for the presence of unchanged alkaloid. In a few cases the amount was estimated biologically.

Codeine sulphate is decomposed promptly by an excess of potassium permanganate in acid, alkaline or neutral solutions, but codeine ultimately reduces from three to six times its weight of potassium permanganate, the behavior being much like that of morphine. It has been suggested that morphine is oxidized with the formation of pseudomorphine, however, pseudomorphine is also decomposed instantly by potassium permanganate.

Moor said that potassium permanganate decomposes strychnine so slowly that it is of no value as an antidote in the presence of organic matter. That statement is misleading. Strychnine sulphate in an alkaline, neutral or acid solution is decomposed rapidly by a great excess of potassium permanganate, but with only a slight excess of the latter the reaction requires several minutes. In one of our experiments, after 50 mg of strychnine sulphate in a slightly acid solution had been treated with six times its weight of potassium permanganate for three minutes, only a trace of strychnine remained. The result was confirmed by the biologic test on frogs. In another experiment strychnine sulphate was treated with its own weight of potassium permanganate in alkaline solution for two minutes, about 90 per cent of the alkaloid being destroyed. In one experiment strychnine sulphate with eight times its weight of blood albumin was treated with eight times its weight of potassium permanganate, that is an amount equal to that of the weight of the albumin, in alkaline solution for two minutes. All but traces of the alkaloid were destroyed. In this case it is plain that the potassium

permanganate acted on the strychnine much more rapidly than on the blood albumin, but it must be emphasized that this was in an alkaline solution, because, while strychnine is decomposed rapidly in an alkaline solution, blood albumin is decomposed more slowly in an alkaline solution. With an acid reaction the conditions would be reversed, albumin being decomposed more rapidly in an acid solution, and strychnine more slowly.

The average fatal oral dose of strychnine is about 2 grains (0.13 Gm) and a solution of an excess of potassium permanganate with sodium bicarbonate will insure the destruction of a large part of the strychnine that may be present in the stomach. Brucine behaves much like strychnine.

Moor stated that potassium permanganate has no oxidizing effect on aconitine or on veratrine. It seems probable that he used impure specimens. An old specimen of aconitine labeled "Aconitine Pure" was found to be but slightly soluble in water, and, when this powder was dusted on a solution of potassium permanganate, decomposition occurred slowly. Some of this powder dissolved in hydrochloric acid was gradually decomposed by potassium permanganate in the course of two minutes. Another specimen labeled "Aconitine Sulphuric Merck, Crystalline" when dissolved in water was decomposed instantly by potassium permanganate. The progress of poisoning by aconitine is so rapid that the physician seldom has an opportunity to apply antidotal measures. Veratrine alkaloid was also decomposed slowly when dusted on a solution of potassium permanganate, whereas veratrine sulphate in solution was decomposed rapidly by an acid, neutral or alkaline solution of that salt.

Phenol reduces potassium permanganate at once in an acid, neutral or alkaline solution. Beechwood creosote is almost insoluble in water, nevertheless, when shaken with a solution of potassium permanganate it is decomposed almost instantly. This is of little importance, however, because the fatal dose of either is about 30 Gm, and each reduces from six to seven times its weight of potassium permanganate. Trinitrophenol is decomposed in either aqueous or alkaline solution. Nitrobenzene is slightly soluble in water and, unlike creosote, only that portion which goes into solution is decomposed rapidly.

Salicylic acid and acetylsalicylic acid are decomposed by potassium permanganate more slowly in alkaline than in acid solutions. Amidopyrine is decomposed almost instantly in an acid, neutral or alkaline solution, and the closely related antipyrine is decomposed promptly by three times its weight of the reagent in an acid solution and much more slowly in an alkaline solution. Acetanilid is decomposed slowly in acid, alkaline and neutral solutions.

Picrotoxin seldom causes fatal poisoning in man, but the closely related wild parsnip frequently causes death. Picrotoxin in an alkaline solution is decomposed by about twice its weight of potassium permanganate in a few minutes, more slowly in acid.

Poisoning of varying degrees by the hypnotics is not uncommon, and, since they are usually taken by mouth, such cases would seem to offer a field for the use of this antidote. The fatal dose of the hypnotics varies from about 2.5 to 10 Gm, and, without definite knowledge of the amount remaining in the stomach, one has no satisfactory guide for the dosage of potassium per-

manganate even in those cases in which it decomposes the hypnotic. Dial and alurate are decomposed immediately in acid, neutral and alkaline solutions. Barbitol, phenobarbital, amytal, neonal, sulphonal and hydrated chloral are either unaffected or decomposed so slowly as to preclude the effective use of potassium permanganate. In the case of dial and alurate poisoning a solution of 1:5,000 may be used to wash the stomach.

Poisoning seldom occurs from the oral administration of a local anesthetic, but our experiments confirm the statement of Moor that cocaine or cocaine hydrochloride is decomposed slowly and, it may be added, whether in acid, alkaline or neutral solutions. Procaine or the hydrochloride is decomposed almost immediately by an excess of potassium permanganate.

Atropine and pilocarpine are also very slowly decomposed in acid, alkaline and neutral solutions. This is in harmony with Moor's results. The greater part of quinine sulphate in a neutral or acid solution is decomposed almost instantly by about twice its weight of potassium permanganate, more slowly in an alkaline solution.

Moor stated correctly that the oral administration of potassium permanganate is useless in atropine, pilocarpine, caffeine, hydrocyanic acid or phosphorus poisoning. Nevertheless, many recent authorities continue to recommend it, especially for the destruction of hydrocyanic acid and phosphorus. However, while hydrocyanic acid is not decomposed rapidly by it in an acid or neutral solution, the addition of sodium bicarbonate insures its instantaneous destruction, but neither acid nor alkali promotes the oxidation of the insoluble yellow phosphorus in substance.

Tea and coffee contain tannin as well as caffeine, and their presence in the stomach is of some importance. Caffeine is decomposed by about its own weight of potassium permanganate, the rate of reaction increasing with the acidity. It begins instantly and is nearly complete in fifteen minutes with 0.4 per cent of hydrochloric acid, but it is not complete in a neutral solution even after several hours when a barely sufficient amount of the reagent is added to caffeine. Tannin is decomposed by potassium permanganate almost instantly.

An attempt was made to determine whether morphine added to an infusion of tea or coffee is decomposed by an amount of the reagent that is insufficient to decompose all the morphine, caffeine and tannin. One hundred and fifty cubic centimeters of an infusion representing 5 Gm. of tea reduced about 2 Gm. of potassium permanganate within a few minutes, and an infusion of coffee was equally active. Hence the presence of tea or coffee in the stomach may exert a greater influence on the decomposition of slowly reacting poisons than a considerable amount of protein. In one experiment, in which morphine sulphate was added to an infusion of tea and the mixture was treated with potassium permanganate for a few minutes, nearly half the morphine escaped destruction in an acid and in a neutral solution. Hence, when morphine is present in the stomach with tea or coffee the amount of potassium permanganate administered should be sufficient at least to decompose the tannin and the morphine. The caffeine is negligible in such cases. Cane sugar is decomposed so slowly that its presence in the stomach may be disregarded. Alcohol interferes with the destruction of some poisons.

CONCENTRATION

The concentration of a solution of potassium permanganate has comparatively little influence on the rate of destruction of certain poisons. A neutral solution containing one part of potassium permanganate to 2,500,000 was decolorized instantly by an excess of morphine, and by amidopyrine, alkaline solutions containing one part of potassium permanganate to 1,000,000 were decolorized almost instantly by a large excess of any of the following: sodium cyanide, hydrocyanic acid, brucine and sparteine, in a neutral solution by pseudomorphine, and in an acid solution by quinine. Three milligrams of strychnine sulphate added to 100 cc. of a 1:100,000 solution of potassium permanganate decolorized an alkaline solution in about three minutes, a neutral solution in six minutes and an acid solution in about half an hour.

SUMMARY

1 Potassium permanganate has a distinct but limited field of usefulness in the treatment of cases of poisoning. Fairly dilute solutions are irritant and concentrated solutions are caustic, while a large dose may cause death.

2 Among the more common alkaloids that give rise to fatal poisoning after their oral administration and for which potassium permanganate may be useful are aconitine, amidopyrine, antipyrine, morphine and strychnine. To these may be added picrotoxin and probably picrotoxin-like substances (wild parsnip). Potassium permanganate may be used for the destruction of hydrocyanic acid and of potassium or sodium cyanide in the stomach, but only in an alkaline solution.

3 The reaction of potassium permanganate with different poisons varies widely, depending on whether they are present in acid, neutral or alkaline solutions.

4 Potassium permanganate should not be depended on to destroy all the poison, and its use should be followed by evacuation of the stomach.

5 Potassium permanganate may be administered orally in concentrations varying from 1:2,000 to 1:5,000, depending on the dose required, and 1:5,000 may be used for washing the stomach.

6 Potassium permanganate is useless in cases of poisoning by atropine, cocaine or yellow phosphorus in substance, or by any one of the greater number of the hypnotics; it may be useful in washing the stomach after poisoning by alurate, dial and possibly some others, not after barbitol, phenobarbital, amytal, neonal, sulphonal or hydrated chloral poisoning. It may be used for washing the stomach in cases of poisoning by phenol or creosote, but it cannot be administered safely in sufficient amounts to decompose an otherwise fatal dose of either.

7 The dose of potassium permanganate and the concentration of the solution should be governed by the nature and the quantity of the substance which it is designed to decompose, and with reference to the other contents of the stomach. Potassium permanganate decomposes protein much less rapidly than it decomposes certain poisons, tannin (from tea and coffee) almost instantly, diluted alcohol within a few minutes and sugar (sucrose) very slowly.

8 There is no justification for the intravenous, subcutaneous or intramuscular injection of potassium permanganate for the destruction of any poison in the circulation.

Clinical Notes, Suggestions and New Instruments

KARAYA GUM ASTHMA

SAMUEL M FEINBERG M.D., CHICAGO

It has been known for a long time that cosmetic preparations frequently cause allergic symptoms, particularly in the respiratory tract. Most of the instances reported and figures cited pertain to facial cosmetics and their orris content. Now it is becoming more and more evident that many other types of preparations, such as are used on the hair for wave-setting purposes, may contain ingredients that give rise to allergic reactions. Among the materials that have been incriminated are lycopodium and linseed. One case of vasomotor rhinitis due to Karaya gum in the hair-waving fluid has been reported.¹ According to the United States Department of Agriculture,² the following ingredients are used in the manufacture of hair fixers: acacia, gum tragacanth, linseed gum, quince seed gum, Karaya gum, boric acid, sodium potassium and ammonium carbonates, alcoholic keratin, coloe, petrolatum, cera-flux, glyco wax A and paraflax.

In this connection the following case is of interest

Mrs F S, a married woman, aged 31, consulted me, Nov 8, 1934, for an asthma of two years' duration. Her attacks would usually last two days, and not a week passed without such symptoms. The longest period that she had ever been free from asthma was one month—during which time she was on a visit in Iowa. Her occupation in the past had been hair-dressing, but in the last year she worked only occasionally because of the debilitating effect of the asthma. She was accustomed to dress her own hair with her favorite waving fluid, and since she could not work regularly she frequently would do hair waving at her home for the convenience of some of her friends. The patient suspected that flour, hair-dressing fluid, face powder, and tobacco might be factors in the causation of the attacks. There was a distinct familial history of allergy: a grandmother and an uncle had asthma and both of the patient's parents suffered from eczema.

Complete skin tests (including linseed) by the cutaneous method revealed a two-plus reaction to wheat, sweet potato and tobacco and a one-plus reaction to orris root. A drop of the hair-waving fluid that the patient used on the site of a small scratch produced a wheal about 2 cm. in diameter. The chemist who prepared the fluid was interviewed and it was learned that the material was a solution of Karaya gum and sodium benzoate in water. The patient was instructed to obtain some of the powdered Karaya gum from the chemist. She was curious to know about the appearance of the powder. At home she opened the box and in two or three minutes an attack of asthma ensued that lasted two days. Subsequently scratch tests were made with the powdered Karaya gum, sodium benzoate, tragacanth, acacia and another brand of hair-waving fluid. All were negative, with the exception of the Karaya gum. The latter gave an enormous reaction.

The patient was instructed to eliminate wheat and sweet potatoes from her diet, to change to orris-free cosmetics and to avoid tobacco smoke. After a test period the asthma still persisted. She was then instructed to remove the hair-waving fluid from her home and never to use it on herself or any one else. In addition she was advised to give her home a thorough cleaning. Following this procedure the asthma disappeared and after a period of six months the asthma has not recurred, in spite of the addition of the wheat and sweet potatoes in her diet and the use of cosmetics containing orris.

This is the second case of allergy and the first of asthma reported as due to Karaya gum in hair-waving fluid. By inquiry it has been ascertained that this material is a common ingredient of many brands of fluids. Karaya gum, or Indian

gum, is a white or gray powder obtained from the sap of a tree, *Angoecus Latifolia* Wall, grown chiefly in India. It can be readily understood that these fluids, after drying on the hair and becoming pulverized, may serve as a prolific source of allergic irritation to the individual herself or to her friends. Occupational exposure must also be kept in mind. No doubt many more undiagnosed cases exist. Karaya gum, because of its property of absorbing water and increasing markedly in bulk, has been used for constipation with similar effects as with the use of linseed, agar and the like. The product known as "Kaba" is made from Karaya gum. This material is also used as an emulsifying agent, as an ingredient of hand lotions and in the process of calico printing. In India it is used in the preparation of sweetmeats.

Attention is called to the importance of giving serious consideration to Karaya gum and similar hair-setting fluids as a possible cause of vasomotor rhinitis, asthma and other forms of allergy.

STUDIES ON CAPILLARY FRAGILITY: A DEVICE FOR THE STUDY OF CAPILLARY HEMORRHAGE

IRVING S CUTTER, M.D., AND CARL A JOHNSON, M.D.
CHICAGO

For a number of years one of us has been interested in studies on the capillaries with particular reference to capillary fragility and capillary leakage by diapedesis. It is felt that both these processes might occur as a result of an acute injury to the capillary vessels, as in scarlet fever, from long standing cardiovascular disease, or as a result of a constitutional weakness of the vessels such as occurs in certain of the blood dyscrasias.

Two types of instruments have been used to obtain an objective index of the capillary injury.

1 The positive pressure method in which a cuff is placed around the upper arm and pressure applied. In certain dis-

Fig 1.—Diagram of the instrument. A is a special mechanical gage graduated from 0, or vacuum to 760 mm of mercury and from 760 to 0 (not shown in the diagram), B is a mercury gage, C is a 300 cc reservoir, D a vacuum pump, E and F are "by pass" needle valves and G is a suction chamber. G is drawn larger in the upper diagram so as to show more accurately its construction.

eases such as scarlet fever, petechiae occur below the cuff, this is known as the Rumpel-Leede phenomenon.

2 The suction method by which negative pressure is applied to a small area and the amount of suction in a given time necessary to produce hemorrhage is measured.

The first of these was devised by Hecht,¹ but for our purpose it was not satisfactory because it is difficult to handle, it is not portable, and accurate measurements cannot easily be made. In 1931 Cutter and Marquardt² described a suction instrument by means of which rupture of capillaries was

From the Allergy Department of Northwestern University Medical School.

1 Bullen, S. S. Perennial Hay Fever from Indian Gum (Karaya Gum). *J. Allergy* 5: 484 (July) 1934.

2 United States Department of Agriculture Food and Drug Administration. Personal communication to the author.

From the Department of Medicine of Northwestern University Medical School.

1 Hecht, A. F. Experimentell klinische Untersuchungen über Haulblutungen im Kindesalter, *Jahrb. f. Kinderh. Ergänzungsheft* 85: 113 1907.

2 Cutter, I. S. and Marquardt, G. H. Studies on Capillary Fragility. *Proc. Soc. Exper. Biol. & Med.* 28: 113 (Nov) 1930.

observed directly with the capillary microscope, but this was not readily adaptable to clinical use.

The instrument here described embodies certain principles that are essential for rapid and accurate work and lends itself with ease to clinical studies.

Figure 1 is a diagrammatic illustration of the instrument. It consists of *A*, a gage graduated from 0 to 760 (mm of mercury negative pressure) and from 760 to 0 (barometric pressure). This gage is connected to *B*, a mercury gage, by which the accuracy of the mechanical gage can be checked when desired. The gage system is connected to *C*, a reservoir with a capacity of 500 cc. and this in turn is connected to *D*, a small rotary vacuum pump, capable of producing a (partial) vacuum down to within 0.25 mm of mercury. There are two 'by pass' needle valves *E* and *F* by which air can be admitted into the system and any degree of vacuum obtained and maintained. The reservoir is also connected by means of a heavy rubber tube to the suction chamber *G*. This is provided with a stopcock so that the suction chamber can be shut off from the rest of the vacuum system. It is observed that the volume of the suction chamber is very small as compared with the rest of the system. This makes a more accurate adjustment possible.

The suction chamber, *G*, is of a special design, the upper surface is flat and the skin area under observation can be visualized during the time that measurements are being taken, and the evolution of the hemorrhages can be observed by means of a lens. (An otoscope furnishes illumination as well as a lens for this purpose.) The hole in the suction cup is 5 mm and the flange is 10 mm. A 5 mm aperture is used because with a larger opening the skin may be sucked into the chamber and hence cause pain in infants and children.

The whole instrument is enclosed in a carrying case measuring 12 by 9 by 9 inches and weighs 20 pounds (fig. 2).

Fig. 2—Appearance of the instrument

To operate, the suction pump is turned on with the stopcock of the suction chamber closed. The desired negative pressure is obtained by adjusting the 'by pass' needle valves. The suction cup is applied to the skin when it is desired to make an observation and the stopcock on the suction cup is opened. No special seal is necessary. The skin over the area is observed (through the suction cup) by means of the lens of an otoscope. The otoscope also furnishes the illumination. The suction is applied for thirty seconds and the number of hemorrhages are recorded. Readings are taken at intervals of 50 mm of negative pressure, although shorter periods may be used.

The skin area most commonly used is the cubital space or the infraclavicular region, as these areas give the most uniform results.

There seem to be two types of hemorrhage, one evidenced by a bright red spot interpreted to be due to capillary rupture, and the second by a darkened more diffuse hemorrhagic area

thought to be due to hemorrhage by diapedesis. These can be distinguished grossly, and experiments are now in progress to determine the microscopic differences between the two lesions.

Results thus far obtained with this instrument indicate that it has a wide field of usefulness in the study of the peripheral vascular bed, with particular reference to the factors under lying capillary hemorrhage.

GLANDULAR PHYSIOLOGY AND THERAPY

GASTRO-INTESTINAL PRINCIPLES

EXCEPTING THOSE HAVING ANTIANEMIC AND CIRCULATORY EFFECTS

A. C. IVY, PH.D., M.D.
CHICAGO

NOTE.—This article and the articles in the previous issues of THE JOURNAL are part of a series published under the auspices of the Council on Pharmacy and Chemistry. Other articles will appear in succeeding issues. When completed the series will be published in book form.—Ed

SALIVARY GLANDS

There is no evidence indicating that a hormone mechanism is significantly concerned in the secretion of saliva. Extracts of the buccal and pharyngeal mucosa fail to stimulate the salivary glands, and the introduction of dilute acid into the mouth does not stimulate the recently denervated submaxillary gland.¹ Stimulation should result if a hormone mechanism is concerned.

It has been shown that, following the stimulation of the peripheral end of one chorda tympani nerve, a choline-like agent appears in the blood, this results in a slight fall in blood pressure and in secretion by the salivary gland on the opposite side. Stimulation of the sympathetic supply of the submaxillary gland is said to cause liberation of an epinephrine-like agent. Whether such principles are elaborated during the mastication of a meal in sufficient amounts to exert a detectable physiologic influence has not been demonstrated.²

Some evidence has been reported purporting to indicate that the salivary glands produce an internal secretion which influences the production of other digestive secretions and even affects sugar metabolism. None of the evidence that has been submitted to date is convincing.³ It is interesting that bilateral ligation of the duct of the parotid gland in the dog increases sugar tolerance in the normal but not in the depancreatized dog.⁴

STOMACH

Gastrin—The secretion of gastric juice following the ingestion of a meal is due only in part to a humoral mechanism. That a humoral mechanism is concerned

has been demonstrated by the secretion of an auto-transplanted gastric pouch following a meal.⁵ The humoral agent or agents may be either absorbed secretagogues present in or arising from the digestion of certain foods (meat, liver or other substances) or the hormone gastrin.

The fraction of liver extract that contains the anti-pernicious anemia substance is rich in gastric secretagogic potency. This fraction stimulates gastric secretion on local application to the gastric and intestinal mucosa. It does not act by being absorbed from the stomach but may act by being absorbed from the intestine. When this fraction is freed of vasodepressor substances, it will stimulate gastric secretion when slowly injected intravenously. Thus, there is an example of a gastric secretagogue that may act by way of a humoral route.⁶ The hormone gastrin is supposed to be elaborated chiefly by the mucosa of the pyloric antrum, and possibly by the mucosa of the intestine, when the mucosa is appropriately stimulated, preferably by solutions containing secretagogues.

An acid extract of pyloric mucosa, when injected hypodermically, stimulates gastric secretion. Crystalline histamine has been isolated from such an extract,⁷ the evidence indicates that it is the sole secretory excitant of such extracts, that is gastrin and histamine appear to be identical. It would appear, then, that histamine is the gastric hormone, if such a hormone exists. If some other substance is the gastric hormone, it has never been extracted from the pyloric mucosa.

Histamine (either the methyl or the ethyl derivative) is the most potent excitant of acid gastric secretion known, and it will stimulate the gastric glands in concentrations that have little or no effect on systemic blood pressure.¹ There is no evidence indicating that histamine has a therapeutic value. It does have a very definite place among the tests of gastric function, namely, to determine whether the gastric glands can secrete free acid. The histamine test is the most rigorous test that may be employed to differentiate between true and false anacidity.⁸

INTESTINE

The mucosa of the upper part of the intestine elaborates two hormones, namely, secretin and cholecystokinin, and the inhibitory principle enterogastrone. The possibility that two other hormones are also elaborated in the upper part of the intestine has been suggested: one is said to stimulate the production of insulin (incretin) and another to augment the motility of the intestine.

Secretin—The discovery of secretin by Bayliss and Starling in 1903 is one of the milestones in endocrinology. In the description of their observations they coined the term *hormone*. They found that when dilute acid is applied to the mucosa of the upper part of the intestine the pancreas is stimulated to secrete its digestive juice. They also showed that the intravenous administration of acid extracts of the duodenal mucosa stimulated pancreatic secretion. It was later

demonstrated that application of acid to a transplanted jejunal loop will cause the transplanted tail of the pancreas to secrete, if the circulation of two dogs is cross-connected and acid is then placed in the duodenum of one of the pair, the pancreases of both will be stimulated to secrete.

It should not be surmised from these crucial experiments that acid is the only substance that causes secretin to be formed. Fatty acids, soaps and peptones are other food substances that cause the duodenum to elaborate secretin.⁹ All attempts to demonstrate that postabsorptive circulating substances originating from food are concerned in stimulating the pancreas to secrete have met with failure.¹⁰

Highly purified preparations of secretin have a slight chologogic and diuretic effect, which is of no practical significance. Similar preparations have no effect on sugar metabolism.¹¹ The isolation of secretin in crystalline form has recently been reported.¹²

Highly purified preparations of secretin have been injected intravenously into man for the purpose of ascertaining whether secretin might be of practical use for estimating pancreatic function. It is too early to state whether secretin will be of value in this regard.¹³ Secretin has no known therapeutic value. It is ineffective when taken by mouth, and it is relatively inactive hypodermically.

Cholecystokinin—The chief stimulus of gallbladder contraction thus far discovered is the hormone cholecystokinin. Stimulation of autonomic nerves in the cat or dog has never been observed to have more than a slight temporary effect on the gallbladder. Attempts to demonstrate that postabsorptive circulating fatty substances originating from food are concerned in gallbladder evacuation have met with failure.

Cholecystokinin may be extracted from the mucosa of the upper part of the intestine of most animals and man. Such extracts, when free from histamine and choline, cause, on intravenous injection, a more or less prolonged contraction of the gallbladder with evacuation in man and animals. That this hormone operates physiologically has been shown by denervating the gallbladder, by cross-circulation and transplantation experiments in the dog and by blood transfusion experiments in man.¹⁵

The most effective excitants for production of this hormone are acids and fats acting in the upper part of the intestine. These substances have little or no action in the lower part. All fats are effective, but egg yolk and cream appear to be the most active. Proteins, particularly meat, rank next, and carbohydrates have little, if any, action.

Cholecystokinin is closely allied chemically to secretin but is probably not identical with it. Preparations of each have been made which are free of physiologically detectable quantities of the other.

This hormone has been shown to be active only on intravenous administration. Since it produces only a quicker, but not greater, effect on the gallbladder than ingested egg yolks and cream, it is not likely that it will prove to be of therapeutic or diagnostic value.

Enterogastrone—It has long been known that undigested fat inhibits gastric secretion and motility, particularly when the fat is in the intestine. This inhibition was formerly thought to be due solely to a nervous reflex mechanism. It was found,¹⁴ however, that the motility of a transplanted gastric pouch was inhibited by ingested fat and that this was not due to the absorption of fat or fatty substances.¹⁵ This has been shown to be true also for the inhibition of gastric secretion caused by fat.¹⁶ Lim and his colleagues found that a crude preparation of cholecystokinin, when injected in large doses, would inhibit gastric secretion.¹⁷ This observation was then examined in detail, and it now appears that the inhibition of both gastric secretion and gastric motility caused by fat is due to a specific substance, which has been called enterogastrone.¹⁸ These observations have been confirmed in my laboratory.

It has been demonstrated recently that a similar mechanism is concerned in the inhibition of gastric motility that occurs when dextrose is present in the upper part of the intestine.¹⁹

Enterogastrone, though it may now be prepared free of vasodepressor and toxic effects in the dog, has not been prepared sufficiently pure for use in man. However, it may prove to be useful in certain cases of "peptic" ulcer after it has been purified, and particularly if it can be shown to be active when given hypodermically.

Islet Stimulating Hormone—Presumptive evidence has been reported indicating that the duodenum produces a hormone (incretin, or duodenin) which stimulates the pancreatic islets to produce insulin.²⁰ In the intact animal, certain fractions of duodenal extract cause a decrease in the hyperglycemia induced by dextrose or by epinephrine, regardless of the mode of administration. Some state that it will reduce the normal blood sugar level. It does not act in the depancreatized dog.²¹ Several observers assert that extracts containing the principle are effective orally in reducing the ketosis and blood sugar in diabetic patients.²²

The latent therapeutic possibilities in the fairly numerous reports now available on this principle justify careful clinical investigation. A theoretical question arises, however, in regard to the probable usefulness of this principle, namely, Should the islets of a diabetic patient be stimulated? Would not such stimulation result in injury?²

THE SECRETION OF SUCCUS ENTERICUS

It is certain that mechanical and chemical stimuli acting locally are the primary factors concerned in the secretion of intestinal juice.¹

Loops of the intestine transplanted into the skin secrete small amounts of juice continuously and are stimulated by local mechanical and chemical stimuli. Following a meal, it is difficult to detect an increase in secretion,²³ although an analytic study reveals some increase in volume of secretion and output of enzymes.²⁴ Thus, a humoral mechanism is apparently concerned in the secretion of succus entericus, but it does not play a predominant rôle.

A GASTRO-INTESTINAL MOTOR HORMONE?

Investigators from time to time have presented evidence purporting to show that gastro-intestinal motility is controlled in part by a hormone mechanism. In most of these studies an extract of intestinal mucosa was used that contained histamine, choline or both. In fact, choline has been called the gastro-intestinal hormone.²⁵ But the studies on which this claim was based are pharmacologic in nature.

In unanesthetized animals choline has variable effects; this is true also of man.¹ Its use in patients is not recommended.

There is some preliminary evidence available indicating that the intravenous injection of certain fractions of duodenal extracts, free from choline and histamine, augments intestinal motility.²⁶ Since the motility of transplanted loops of intestine is not definitely increased after the ingestion of a meal,²³ it would appear that if a hormone is concerned in regulating gastro-intestinal motility it is not readily detectable.

SUMMARY OF GASTRO-INTESTINAL HORMONE THERAPY

Although the gastro-intestinal hormones are of great physiologic interest, none of them have been definitely demonstrated to possess therapeutic value.

ADMINISTRATION OF PEPSIN

Pepsin as a therapeutic agent has passed through several periods of popularity since its discovery in 1835. In spite of this, practically no scientific evidence has been submitted showing that it is of real therapeutic value.

Theoretically, pepsin with adequate hydrochloric acid is indicated in achylia gastrica, particularly in those patients who complain of flatulent dyspepsia and diarrhea. Although such therapy is not infrequently employed in achylia gastrica, clinical reports are at variance in regard to the importance of the pepsin. Most of the recent reports indicate that hydrochloric acid alone is sufficient, however, others report that some patients do better after pepsin is added to the acid.²⁷

In the presence of gastric anacidity there is some evidence indicating that, after the adequate administration of acid, a normal amount of pepsin may be secreted by the gastric glands. In such patients the addition of

pepsin to the acid is superfluous.²⁸ Whether the stomach of a patient manifesting anacidity will secrete adequate pepsin on the administration of acid can be determined only by fractional gastric analysis.

Recently several brief clinical reports have appeared, indicating that the administration of desiccated hog's stomach (ventriculin) may be as effective as hydrochloric acid in relieving the dyspeptic symptoms and diarrhea in patients having achylia gastrica and anacidity.²⁹

Pepsin has been administered subcutaneously to patients having a "peptic" ulcer,³⁰ the claim has been made that pepsin plays a specific role. Both favorable and unfavorable reports on this therapy have been made. The rationale on which such therapy is based and the clinical reports now available are not sufficiently impressive to warrant a statement concerning the details of the therapy.

THE ORAL ADMINISTRATION OF RAW PANCREAS AND PANCREATIN

Experimentally it is established that the absolute exclusion of pancreatic juice from the intestine in the dog results in polyphagia, the passage of large bulky stools, and a considerable disturbance of the digestion and absorption of fat and protein, and to a lesser extent of that of carbohydrate.³¹ It is also true that some dogs are much more affected than others and that the same dog may manifest considerable fluctuation from time to time in the capacity to utilize food fat. More than half of the dogs manifest progressive inanition and die unless large quantities of easily digested foods are supplied with a liberal supply of vitamins. Even this fails not infrequently after from six to ten months.

Many laboratory workers who have experimented in this field³² have added raw ground pancreas in relatively large amounts (from 50 to 200 Gm daily) to the diet of depancreatized dogs controlled with insulin and to the diet of dogs with absolute exclusion of the pancreatic juice from the intestine. With raw pancreas in the diet, such dogs have remained in excellent condition for several years, this is not otherwise the case, except in rare instances.³³

The mechanism of the effect of such therapy is not simple. Raw ground pancreas was originally administered with the hope that some of the contained enzymes would pass through the stomach without being inacti-

vated by the acid of the gastric juice.³⁴ However, this has never been demonstrated by direct experiment on dogs with duodenal or jejunal fistulas.³⁵ There is evidence, though meager, indicating that the administration of raw pancreas, pancreatin (from 10 to 20 Gm), or pancreatic juice to depancreatized dogs, or dogs deprived of pancreatic juice, decreases the fat lost in the feces,³⁶ as well as the nitrogen.³⁷ Whether this is due to improved digestion or absorption has not been settled, though the latter appears chiefly to be concerned. Further, in interpreting the changes in fecal fat loss, one has to consider also the possibility of changes in the excretion of fat by the intestinal mucosa. The problem is rendered more complex, yet more important, by the more recent reports that the lecithin and choline content of the raw pancreas, rather than the enzymic content, is chiefly responsible for the better nutrition and greater longevity of insulin-controlled depancreatized dogs. The administration of raw pancreas, lecithin or choline prevents the marked fatty infiltration of the liver and hepatic insufficiency.³⁸

The clinical literature prior to 1912 contains reports on a few well studied patients with pancreatic deficiency in whom the administration of raw pancreas or pancreatin decreased the fecal loss of fat and nitrogen.³⁹ Since then very little clinical investigation has been reported.⁴⁰ The survey of Bastedo²⁷ in 1925 indicated that pancreatin was not being widely used except in tropical sprue and pancreatitis. Pancreatin and raw pancreas are still being used in sprue,⁴¹ although their value has not been definitely demonstrated by a thorough study. It has been reported that in sprue the concentration of enzymes in duodenal contents is normal,³⁸ but this does not mean that the total output is normal. Pancreatin therapy has been recently reported to be of value in the treatment of arthritis deformans⁴² and scleroderma.⁴³

SUMMARY

The administration of adequate amounts of raw pancreas or active pancreatic extracts orally in the presence of a deficiency of the external pancreatic secretion has a firm theoretical basis. The value of raw pancreas given orally to depancreatized dogs is established, the chief value of the therapy apparently being to prevent fatty degeneration of the liver. There is some evidence indicating that administration of raw pancreas and pancreatin to animals and patients having a definite deficiency of pancreatic secretion decreases the loss of fat and nitrogen in the feces. Such therapy has been used in sprue and other conditions, but its value in these has not been definitely established.⁴⁴

HOWARD A. CARTER, Secretary

TISSUE HEATING BY SHORT WAVE DIATHERMY

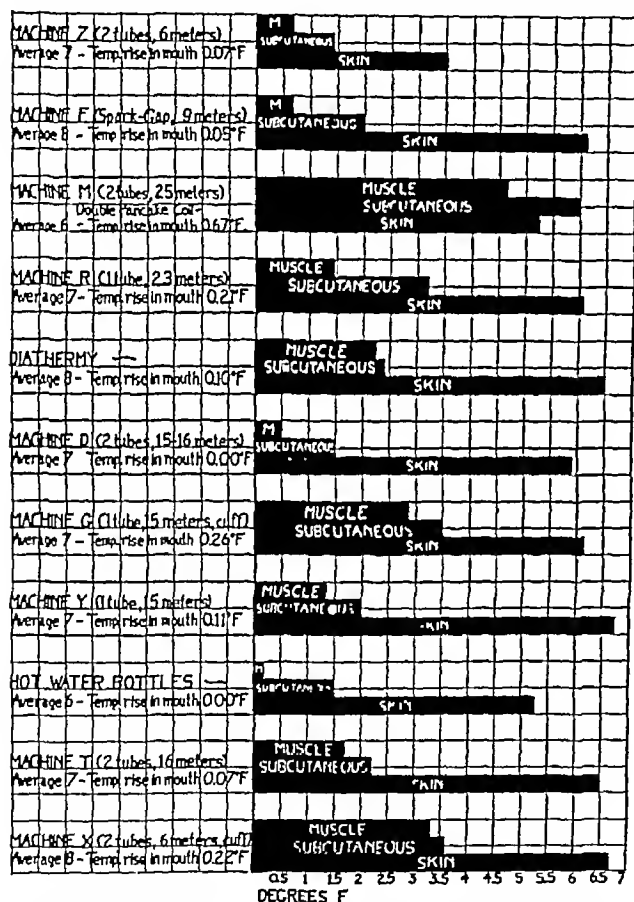

BERNARD MORTIMER, PH D, MD

AND

GERTRUDE BEARD, RN

CHICAGO

Following the technic described in a previous article,¹ nine new short wave diathermy machines were tested for their ability to heat the tissues of the human thigh. As before, the machines were used in rotation, and the

Temperature rises in human thigh Current on for twenty minutes
Technic directed by the manufacturers Dosage regulated by tolerance
of patient.

dosage was regulated entirely by the tolerance of the patient. A representative of each manufacturer was present at one test to direct the usage of his machine.

The machines submitted were (wavelengths listed are those quoted by the manufacturers)

- Machine X—2 tubes, 6 meters
- Machine T—2 tubes, 16 meters
- Machine Y—1 tube, 16 meters
- Machine G—1 tube, 15 meters
- Machine D—2 tubes, 15-16 meters

Aided by a grant from the Council on Physical Therapy of the American Medical Association

From the Department of Physiology and Pharmacology and the Department of Physical Therapy Northwestern University Medical School
1 Mortimer Bernard, and Osborne S L Tissue Heating by Short Wave Diathermy Some Biologic Observations J. A. M. A. 104: 1413 (April 20) 1933

- Machine R—1 tube, 23.31 meters
- Machine M—2 tubes, 25 meters
- Machine F—Spark-gap, 9 meters
- Machine Z—2 tubes, 6 meters

A conventional spark-gap diathermy machine was used for comparison

In addition to the machines listed, it was decided to run comparable tests with two hot water bottles, one on the medial and one on the lateral aspect of the thigh. The temperature of the bottle was maintained at from 43 to 45 C by an electrical heating element inserted through a rubber stopper

Temperatures of the skin, of the subcutaneous tissue and of the muscle (quadriceps extensor) were taken before and after a twenty minute clinical application by the thermocouples and potentiometer described previously. Mouth temperatures were also recorded. The accompanying graph illustrates the results that were obtained

Since several manufacturers had submitted cuff electrodes as additional equipment, two tests were carried out using cuffs with the conventional diathermy machine. The following average temperature increases were observed

Skin, 88 degrees F

Subcutaneous tissue, 9.95 degrees F

Muscle, 88 degrees F

To date fourteen short wave diathermy machines with wavelengths ranging from 6 to 25 meters have been tested for their ability to heat the tissues of the human thigh. From our results there appears to be no advantage of any one wavelength over another for heating purposes

PRELIMINARY REPORT OF THE COUNCIL

THE COUNCIL HAS AUTHORIZED PUBLICATION OF THE FOLLOWING
PRELIMINARY REPORT

PAUL NICHOLAS LEECH, Secretary

IMMUNE GLOBULIN (HUMAN) PLACIM- MUNIN-SQUIBB, AND IMMUNE GLOBULIN (HUMAN)- LEDERLE

Immune Globulin (Human) is the protein material obtained from human placentas by extraction with saline solution and refined by precipitation with ammonium sulphate. It is referred to in the literature as "placental extract." The National Institute of Health has licensed its manufacture under the name "Immune Globulin (Human)"

Two firms, E. R. Squibb & Sons and Lederle Laboratories, Inc., have presented preparations for consideration of the Council, the one under the name "Placimmunin," the other under the name "Immune Globulin (Human)-Lederle." These products will be discussed individually later in this report

The experimental clinical work on the use of Immune Globulin (Human) has been done by McKhann and his co-workers, principally Chu. They found that the product apparently prevented (and in a few cases modified) measles in children exposed to the disease. The rationale for the use of placental extract was the natural immunity of the new born to certain diseases, including measles¹

The use of the globulin in place of the serum is apparently for concentration purposes. There is probably not a great deal of difference in potency. Schick and Karelitz² say "the

1 McKhann, C. F. and Chu, F. T. Antibodies in Placental Extracts. J. Infect. Dis. 52: 268 (March-April) 1933
2 Schick, Béla and Karelitz, Samuel. Studies in Prophylaxis of Measles. Am. J. Dis. Child. 47: 1162 (May) 1934

globulin fraction of the serum was tested. The results indicated that this fraction was at least as effective and probably slightly more effective than the serum from which it was extracted."

There has been no proof submitted to the Council to show that the globulin varies appreciably from the serum from the same source. Therefore the product is not entirely original, at least as far as is shown in the available evidence.

The first series of forty-three cases³ is reported in groups of children treated simultaneously. A table has been made from the articles by McKhann and others.⁴

These case histories³ show that placental extract is at least as efficacious as convalescent serum or adult whole blood for this purpose (i. e., prevention). It is also apparent that, with these dosages, prevention usually occurs even when modification is attempted. This is demonstrated clearly in the report of McKhann and Coady⁴ and even in McKhann's summary,⁴ prevention occurred in seven out of twenty-five cases in which modification was attempted. (N. B. Those who desire further information in regard to tabulation of preventions, modifications, and failures are referred to McKhann's latest article,⁵ which was published after the formulation of this report.)

In an analysis of twenty-one partial or complete failures by McKhann,⁴ it is pointed out that the five modifications marked a were "early cases treated when preparations and dosages were

On the basis of the available data, the only indicated procedure would be the use of a dose which ordinarily or in most cases would prevent measles, other factors being equal, with the hope that modification would result in many cases for the benefit of the individual. There is no evidence at the present time to indicate reasonable assurance of prevention of typical measles under certain circumstances, if the dosages recommended for modification were used. The number of tests is as yet inadequate to permit the exact determination of the best fraction of the extract to use and the dosage required for children of various ages and at various stages of the incubation period of the disease.

The Council is informed that reactions following the injection of placental extract, although infrequent, appear to be due in large measure to the inclusion in the finished extract of variable amounts of a specific tissue protein. It is pointed out that the aging of the placentas before preparation of the extract, with the autolysis of the tissues, must be considered as a possible factor. The Council holds that commercial products should be demonstrably effective in bringing about the results claimed for them and further that they should be made as free from reactions as possible.

Placimmunun—E. R. Squibb & Sons presented this preparation for the Council's consideration principally for approval of the name. The firm felt that additional data were necessary

very varied." In regard to the sixteen other results thus classed, marked b he states that they "occurred in attempts to determine adequate dosage of refined preparations in relation to time of administration." It is also evident that the unfiltered preparations are more potent than the filtered.

The reason for the development of this product is apparently the limited availability of convalescent serum and the feeling that placentas will be an adequate source for these immune factors.

The Council is of the opinion that the available evidence is insufficient on which to base recommended dosages, especially when those dosages are specifically designated as adequate for prevention or for modification. It would be preferable if clinical evidence from other sources were available to substantiate these dosages. The results were not especially uniform in obtaining modification when it was desired.

There are many factors that go to make up the adequate dose which will modify and yet prevent typical measles.

The intimacy of exposure, the length of exposure, the stage of the disease at the time of exposure, the virulence of the infection, the individual resistance, the lapse of time between exposure and immunization and the potency of the immunizing agent all influence this problem of adequate dosages to accomplish modification.

before the product could logically be presented to the medical profession. The Council's Committee on Nomenclature, although feeling that the term *Placimmunun* is somewhat unfortunate since it suggests that the product represents a new class of immunizing substances parallel to vaccines and the like, recommended that the name '*Placimmunun*' be recognized on the ground that it is fair to presume that placenta offers, at least, an additional source of the immunizing substance, the supply of which may otherwise be inadequate. The Council voted to recognize the name '*Placimmunun*' for the placental extract submitted by E. R. Squibb & Sons under that name provided the written consent of Dr. McKhann and his associates was secured by the firm and submitted to the Council. Subsequently the formal consent of Dr. McKhann and his associates was received by the Council.

The label for *Placimmunun* bears the following dosage statement:

Prophylactic 3.5 cc single dose
Therapeutic 5 cc., repeat as required

In the information presented by the firm there occurred the following statement:

Therapeutic Indications: Used in children as a prophylactic and therapeutic [agent] against measles. It is standardized with diphtheria toxin. No advertising issued.

The firm has recently submitted an advertising circular for the product to which the Council's referee has found no objection. It is believed that the prophylactic dose is probably adequate to prevent measles under ordinary circumstances if the potency is equal to that of McKhann's preparation.

Immune Globulin (Human)-Lederle—This product was submitted for the Council's consideration as a "measles modifier."

³ McKhann C. F. and Chu F. T. Use of Placental Extract in the Prevention and Modification of Measles. *Am. J. Dis. Child* 45: 475 (March) 1933.

⁴ McKhann and Chu³ McKhann C. F. and Coady H. Immunity in Infants to Infectious Diseases. Placental Antibodies. *South Med. J.* 27: 20 (Jan) 1934. McKhann. Totals in table 3 (not published elsewhere).

⁵ McKhann C. F. Green A. A. and Coady H. *Pediat* 6: 603 (May) 1935.

In a submitted circular, the firm emphasizes the variability of adequate dosage for the modification of measles in the following statement

"The strength of IMMUNE GLOBULIN (HUMAN) LEDERLE has been adjusted so that it is believed that 2 cc will usually modify the attack of measles if it be injected on the sixth or seventh day after exposure

In McKHANN'S later study it has been found that the dose required to modify the attack without preventing it or stopping it increases according to the length of the time interval between the date of the contact (exposure to measles) and the date on which the Immune Globulin is injected

Thus if 2.0 cc is the effective dose at the 7th day after contact then 1.0 cc should be sufficient on the 2nd or 3rd day but 10.0 cc would be needed if symptoms (fever, coryza etc.) have been present for 2 or 3 days

Still later experiences indicate that the dosage of the IMMUNE GLOBULIN must vary somewhat according to the intimacy of the exposure

On the other hand the physician must bear in mind that too large a dosage of the Immune Globulin tends to prevent the development of even the modified attack in which event the permanent active immunity would probably not be established

The physician should adjust the dosage in accordance with his knowledge of the circumstances

Thus last statement will probably always be true as far as the actual amount required for each individual case is concerned. There should be, however, more evidence available and more proof of the adequacy of these dosages in most cases, before the physician can accurately adjust such a basic dose to meet individual requirements

The 2 cc trade package contains this recommendation "To modify measles inject 2 cc. on the 6th or 7th day after exposure" This is questionable, because such procedure with this amount might be inadequate at that time to insure against

TABLE 2—McKhann and Coady

	Total Number of Cases	Preven- tion of Measles	Modifi- cation of Measles	Typical Case of Measles
Placental extract to prevent	95	91	4	0
Placental extract to modify	8	6	3	0
Convalescent serum or adult whole blood	33	20	4	0
No treatment	2	0	0	2

typical measles (unless this commercial product is more potent than McKhann's preparation)

The Council is of the opinion that the circular "Immune Globulin (Human) Lederle Measles Modifier" should be rewritten to include mention of the prevention factor and to contain more substantial evidence of adequate dosage

In conclusion, the following points are of importance

1 The variation in potency between placental serum and globulin is apparently not marked and has not been demonstrated

TABLE 3—McKhann

	Total Number of Cases	Preven- tion of Measles	Modifi- cation of Measles	Typical Case of Measles
Unfiltered placental extract to protect	95	90	5a	0
Unfiltered placental extract to modify	3	1	2	0
Refined filtered placental extract to protect	157	142	6b	9b
Refined filtered placental extract to modify	25	7	17	1b

2 The product is as efficacious for prevention as convalescent serum and is derived from a more adequate source

3 The clinical results show sufficient evidence to warrant recommended doses for prevention those for modification are questionable on the basis of available evidence

4 Clinical reports from other sources in confirmation of the results are desirable

5 The standardization of this product on the basis of its neutralizing effect on diphtheria toxin seems adequate only if there is a definite ratio between the diphtheria immune and measles immune factors in the globulin (McKhann's latest report⁶ would seem to indicate that this ratio is not definite)

The standardization on the basis of a clinical trial on measles contacts does not appear to be adequate, but the details of the procedure have not been given and final judgment cannot be made until they are known

CONCLUSION

After considering the available evidence, the Council decided that although Immune Globulin (Human) appears to be a promising immunizing agent, more evidence of its value is needed before it may be generally used by the medical profession

The Council therefore postponed consideration of Immune Globulin (Human), and the brands submitted by Squibb (Placimmunin), and Lederle, until such further evidence is available, and authorized publication of the foregoing report.

Committee on Foods

THE COMMITTEE HAS AUTHORIZED PUBLICATION OF THE FOLLOWING
REPORT
RAYMOND HERTWIG Secretary

NOT ACCEPTABLE

LACTO-DEXTRIN

The Battle Creek Food Company, Battle Creek, Mich., submitted to the Committee on Foods a product essentially lactose, dextrin, soluble starch and lemon powder called "Lacto-Dextrin"

Manufacture—Dextrin is prepared by diastatic enzyme hydrolysis of cooked cereal starch in a water suspension. Lactose equivalent to the dextrin yield (calculated on dry basis) is added. The mixture is dried at 42 C., admixed with an equal weight of dried lactose and 1 per cent of lemon powder, pulverized and sealed in tins

Analysis (submitted by manufacturer) —

	per cent
Moisture	4.6
Ash	0.2
Fat (ether extract) less than	0.1
Protein (N x 6.25) less than	0.2
Reducing sugars as lactose	75.6
* Soluble starch	2.9
Dextrins (by difference)	14.4
Titrate acidity as citric acid	0.2

* Browne's Hand Book of Sugar Analysis p 509

Discussion of Advertising—The advertising presents Lacto-Dextrin as "A special carbohydrate food for changing the intestinal flora an antitoxic food (it) combats autointoxication is not a medicine, but is most efficient for changing the intestinal flora—that is, for suppressing and destroying the poison-producing germs found in the intestinal tract. At the same time, Lacto-Dextrin builds up an army of protective or friendly germs. This is nature's way of preventing and opposing many common diseases. Lacto-Dextrin banishes intestinal poisons which may cause the acid condition (acid stomach) changes a putrefactive flora to a normal acidophilic flora by changing the culture medium (the bowel is always a culture medium for bacteria) from one that favors putrefactive organisms to one that is agreeable to fermentative bacteria when intestinal putrefaction occurs in the infant, as well as in the adult, a rational treatment is afforded in the use of Lacto-Dextrin an aid in the treatment of intestinal toxemia

provides the proper nutrient medium for promoting the growth of the normal protective organisms which combat putrefactive bacteria in the bowel can be depended on to counteract putrefactive organisms when the proper soil is supplied.

Providing culture material for the acidophilic bacteria is an effective method of combating putrefaction, inasmuch as the two bacterial groups are antagonistic. Battle Creek Lacto-Dextrin provides the soil for the development of the acid forming bacteria which, in the proper medium, inhibit the development of the proteolytic organisms and thus restore the normal flora taken in normal doses, a goodly portion reaches the colon before it can be absorbed and the protective bacteria B. Acidophilus and B. Bifidus at once begin to flourish

and soon outgrow the pernicious Welch's Bacillus, B. Putrificus and other harmful organisms. The symptoms of auto-intoxication begin to improve. A great burden is lifted from the liver and kidneys, and other vital organs whose function is to destroy and eliminate poisons. Headaches, bad breath, lassitude and other toxic symptoms disappear and a general improvement in health is experienced as putrefaction in the colon is gradually suppressed and the protective flora becomes dominant. This is the normal way to build health."

Dose—"HOW TO TAKE"—Begin with two tablespoonfuls dissolved in a glassful of hot or cold water three or four times daily. Gradually increase the amount to three tablespoonfuls and continue until the normal flora is restored.

"HOW MUCH TO TAKE"—If gas is produced in such quantities as to cause inconvenience, reduce the amount to a level tablespoonful or even less if necessary. Gas production is evidence that the food remedy has reached the colon where it is needed and in sufficient amount to be effective.

"WHEN TO TAKE"—Lacto Dextrin may be taken at meals or between meals, a half hour before meals when appetite is excessive and after meals when the appetite is poor."

The implantation of acidophilic organisms in the intestine is an uncertain procedure even when large doses of acidophilic culture are fed with or without accompanying lactose. The transformation of intestinal flora merely by feeding lactose and dextrin has not been found to be beneficial except in occasional selected cases. Lactose and dextrin alone cannot create B. acidophilus. The person who is to be thus benefited must have B. acidophilus in his intestine at the start, and many people ordinarily do not harbor B. acidophilus in their intestine.

Because (1) the product Lacto-Dextrin is not considered useful in the manner portrayed in the claims and (2) the advertising to the public is of a medicinal character involving self diagnosis and self treatment, the product will not be listed among the accepted foods of the Committee on Foods.

ACCEPTED FOODS

THE FOLLOWING PRODUCTS HAVE BEEN ACCEPTED BY THE COMMITTEE ON FOODS OF THE AMERICAN MEDICAL ASSOCIATION FOLLOWING ANY NECESSARY CORRECTIONS OF THE LABELS AND ADVERTISING TO CONFORM TO THE RULES AND REGULATIONS. THESE PRODUCTS ARE APPROVED FOR ADVERTISING IN THE PUBLICATIONS OF THE AMERICAN MEDICAL ASSOCIATION AND FOR GENERAL PROMOTION TO THE PUBLIC. THEY WILL BE INCLUDED IN THE BOOK OF ACCEPTED FOODS TO BE PUBLISHED BY THE AMERICAN MEDICAL ASSOCIATION.

RAYMOND HERTWIG Secretary

GREETINGS BRAND PINEAPPLE JUICE UNSWEETENED

Distributor—Alexander & Baldwin, Ltd., Honolulu, Hawaii.
Packers—Kauai Pineapple Company, Kalaheo, Kauai, Baldwin Packers, Ltd., Lahaina, Maui and the Maui Pineapple Company, Kahului, Maui (subsidiaries).

Description—Canned unsweetened pineapple juice retaining in high degree its natural vitamin C content.

Manufacture—Juice drained from crushed pineapple before cooking and pressed from crushed pineapple tissue is blended, 'flash' processed and canned.

Analysis (submitted by distributor) —

Moisture	per cent
Ash	85.0
Fat (ether extract)	0.4
Protein (N x 6.25)	0.01
Reducing sugar as invert sugar	0.3
Sucrose	9.3
Crude fiber	3.8
Carbohydrates other than crude fiber (by difference)	0.01
Titrateable acidity as citric acid	13.4
Alkalinity of ash (cc. normal acid solution per gram ash)	0.9
	10.7

Calories—0.6 per gram 17 per ounce

Vitamins—Chemical assay shows retention of about 90 per cent of the vitamin C of the fresh juice.

Claims of Distributor—For all uses of pineapple juice. Retains in high degree the natural nutritional values of fresh pineapple juice. Good source of vitamins B and C and contains A and G.

COLONIAL BREAD LONG, SLICED AND UNSLICED

COLONIAL PULLMAN BREAD A SPECIAL SANDWICH LOAF

Manufacturer—Colonial Baking Company, Cedar Rapids and Des Moines, Iowa

Description—White breads made by the sponge dough method (method described in THE JOURNAL, March 5, 1932, p. 817), prepared from flour, water, sucrose, powdered skim milk, lard, yeast, salt, malt extract and a yeast food containing calcium acid phosphate, ammonium sulphate, sodium chloride, potassium bromate, potassium iodate and corn starch.

KRIM-KO CHOCOLATE FLAVORED DRINK

Bottlers and Distributors—

Loud and Jackson Dairies, Inc., Jackson, Mich.
Marsh Dairy Company, Winchester, Ky.
McIrvin Dairy, Chillicothe, Mo.
Melville Dairy, Burlington, N. C.
J. M. Miller Dairy, Culver, Ind.
Miller Dairy Products Company, Metropolis, Ill.
Monticello Dairy, Inc., Charlottesville, Va.
Northern Dairy Company, Ishpeming, Mich.
Pestigo Dairy Company, Marinette, Wis.
Frank Petelinz Dairy, Newburgh, N. Y.
Pine State Creamery Company, Raleigh, N. C.
Pipkin Dairy, Lakeland, Fla.
Quality Dairy Company, Hannibal, Mo.
Riverdale Supreme Dairies, Salamanca, N. Y.
Rowan Creamery, Inc., Salisbury, N. C.
Ruff's Dairy, St. Clair, Mich.
Sanitary Milk Company, Kalamazoo, Mich.
Sebree Dairy, Canton, Ill.
Smith Dairy, Midland, Mich.
Sprague Dairy, Flint, Mich.
Steffen Ice and Ice Cream Company, Arkansas City, Kan.
Steffen Ice and Ice Cream Company, Wichita, Kan.
Torrington Creamery, Inc., Torrington, Conn.
Van Eepoel Dairy Products, Inc., Tampa, Fla.
Wauchula Creamery Company, Wauchula, Fla.

Licenser—Krim-Ko Company, Chicago, manufactures the Krim-Ko Chocolate Flavored Drink. Base and licenses its use, the name Krim-Ko and standard advertising under definite contract conditions.

Description—Pasteurized chocolate flavored sweetened skim milk, contains skim milk (from 0.5 to 1.5 per cent milk fat), sucrose, chocolate and cocoa tapioca flour, salt and traces of tartaric acid and agar, flavored with vanilla, vanillin and coumarin. See Krim-Ko Chocolate Flavored Drink (THE JOURNAL, June 30, 1934, p. 2187).

BUDDIE BRAND EVAPORATED MILK

Distributor—Howard E. Jones & Company, Baltimore

Packer—The Oatman Condensed Milk Company, Dundee, Ill.

Description—Canned, unsweetened evaporated milk, the same as Oatman's Brand Evaporated Milk (THE JOURNAL, April 16, 1932, p. 1376).

1. HERSH'S BEST BRAND TOMATO JUICE
2. MINUTE MAN SPECIAL TOMATO JUICE
3. UNITED SERVICE BRAND TOMATO JUICE

Distributors—1. L. F. Hersh & Brother, Elizabeth, N. J.
2. Falk & White Company, Lawrence, Mass.
3. United Service Stores Boston.

Packer—Vincennes Packing Corporation, Vincennes, Ind.

Description—Pasteurized tomato juice with added salt, retains in high degree the natural vitamin content of the raw juice. The same as Alice of Old Vincennes Tomato Juice (THE JOURNAL, Feb. 20, 1932, p. 640).

OUR BRITISH VISITORS

Elsewhere in this issue (Association News, page 518) appears an account of the entertainment of our British visitors, who this week passed through the United States en route to the meeting of the British Medical Association in Melbourne, Australia. Another large group of tourists made the trip by way of Canada. The group that passed through our country included not only four representatives of the official bodies of the British Medical Association but also many distinguished British physicians whose names mean much in the fields of science and medical literature, and a great number of general practitioners from various parts of the British dominion.

In New York the visitors were met on the *Georgic* by representatives of the New York State Medical Society and the American Medical Association. An official reception was held before the boat docked. They were entertained with a tour into the country under police escort and with a dinner for the leading officials on August 4. On August 5 they were shown through the leading medical institutions in New York City and also made a visit to Radio City and the music hall, ending their official visit with a luncheon at the Waldorf-Astoria. In Washington, D. C., they were received at the White House, visited all the notable buildings and were tendered a luncheon by representatives of the Medical Society of the District of Columbia and of the various official medical associations in the capital city. In Chicago the visitors were taken on a tour through the city to see the various medical institutions and were given a luncheon at the stockyards and a tea at the Edgewater Beach Hotel, completing the day with a dinner at the Hotel Stevens and with several private parties. Arrangements have also been made by the official medical organizations of New Mexico, Williams, Ariz., Los Angeles and San Francisco to provide suitably for our British guests.

Dr. E. Kaye Le Fleming, chairman of the council of the British Medical Association, Dr. G. C. Anderson, secretary, Dr. N. Bishop Harman, treasurer, and Dr.

H. G. Dain, deputy chairman of the representative body, expressed the warmest gratitude for the manner in which American colleagues had made them welcome. Moreover, such noted guests as Prof. John Bright Banister, Sir Comyns Berkeley and Sir Ewen Maclean, distinguished obstetricians and gynecologists, were hearty in their praise of American advancement in these fields. Sir Henry Gauvain, noted authority on surgical tuberculosis, and Prof. Ernest William Hey Groves, author of one of the most widely used textbooks in surgery, complimented American institutions and gave demonstrations and lectures en route.

Among the noted guests in the party are George Carmichael Low, renowned for his contributions in the field of tropical medicine, Albert Clifford Morson, urologist, Sir James Purves-Stewart, neurologist, David Waterson, anatomist, and Prof. Robert Hughes Parry, medical officer of health and pathologist.

The party included also a goodly number of women physicians, distinguished ladies and charming young people.

The American Medical Association was glad to extend the hand of greeting officially to our British colleagues and to provide for their entertainment. They in turn, by the warmth of their appreciation and cordiality, did much to cement the friendship between the physicians of the two great English speaking nations.

IMMUNE GLOBULIN (HUMAN) AND MEASLES

Recently THE JOURNAL pointed out that in 1859 life, on the average, ended at 40. The intervening years have brought great advances in the prevention of disease. Adequate research applied clinically has made available many protective measures that aid in the prolongation of life. Today, life expectancy at birth is 57 years.¹ In the acquisition of these seventeen additional years of life the protection against many of the diseases peculiar to infancy, childhood and adolescence has been significant. Unfortunately, however, there has been no suitable measure for dealing with one of the most infectious of all childhood diseases, measles. Any effort to provide a satisfactory weapon with which to combat this disease or to lessen its complications is most commendable. A study of the problem by McKhann² and his co-workers has resulted in the discovery of a new source of immune substance that is apparently capable of modifying or preventing the disease.

The first attempt to modify measles is presumed to have been made by a German physician more than thirty years ago.³ He employed convalescent serum in the early stages of the disease. Park and his associates

¹ The Prolongation of Human Life editorial J. A. M. A. 105: 202 (July) 1935.

² McKhann C. F. and Chn F. T. The Use of Placental Extract in the Prevention and Modification of Measles, Am. J. Dis. Child. 45: 475 (March) 1933.

³ Beckman Harry. Treatment in General Practice, Philadelphia, W. B. Saunders Company 1931, p. 93.

were the first to make use of the serum in this country. The first published report on the procedure was made by Nicolle and Conseil.⁴ Since then other workers have used convalescent serum in modifying the disease. It is frequently used today in the hope of preventing or at least modifying typical measles. The serum has the disadvantage of not being available in adequate amounts at all times.

In 1925 Tunnichiff⁵ found that the serum of a goat convalescing from a reaction to the inoculation of a "green producing diplococcus" was capable of protecting rabbits against a subsequent injection of infective material from patients with measles. Even though it was not known definitely that rabbits were susceptible to human measles, this work was used as a basis for clinical study. Hoyne and Gasul⁶ and later Tunnichiff and Hoyne⁷ found it useful in children over 6 months of age if used before the fifth day of exposure. They stated that protection seemed assured in about 90 per cent of these cases.

McKhann and his co-workers,⁸ observing the natural immunity of the new-born to various diseases, including measles, injected an extract derived from human placentas in an attempt to modify and prevent the disease. For this product they claim an adequate source at all times. Two commercial preparations of the extract (Immune Globulin [Human]) are available at present. The extract was first used by McKhann and his co-workers in institutional cases. This procedure facilitates careful clinical notes and accurate records but, as Levitas⁹ points out in this issue of *THE JOURNAL*, it would not seem to be an accurate estimate of its usefulness. Routine hospital procedure, after the discovery of a case in the wards, and the fact that the contacts are not ordinarily intimate, results in an indefinite degree of exposure. It is generally more definite in cases seen at home, but accurate notes and records are more difficult to obtain under these circumstances. These factors are of interest, especially in view of the standardization of one of the commercial products against measles contacts. The other commercial product is tested against the diphtheria toxin neutralizing effect of the extract. McKhann's¹⁰ latest paper suggests that this method is not entirely satisfactory, because the two immune factors are present to a different degree in different portions of the extract.

McKhann's results have been satisfactory, and the preparation holds promise of being a useful agent in

the prevention and modification of measles. The Council on Pharmacy and Chemistry, in a preliminary report on Immune Globulin (Human) on page 510 of this issue of *THE JOURNAL*, defers consideration until more evidence is available. One of the principal questions requiring additional study is the dosage of this immunizing agent. Frequently, when McKhann¹¹ was attempting to modify the disease, prevention resulted, in some cases modification occurred, and occasionally typical measles developed. This is not surprising in view of the many factors involved in estimating adequate dosage, length of exposure, individual resistance, intimacy of contact, and elapsed time between exposure and injection. McKhann¹⁰ has noted that, because of the short duration of the resultant immunity, it is doubtful whether its use to protect against measles outside of institutions, or in special cases, is justifiable. He points out that, if it is used to modify measles, a permanent immunity would probably result from the ensuing modified disease. He expresses the opinion (and notes that it is not adequately substantiated at present) that modified measles is not known to be followed by complications which render the unameliorated disease a menace.

Several instances of reactions following the use of this agent have been reported, and McKhann concludes his latest paper¹⁰ as follows:

Reactions following the injection of placental extract, although infrequent, appear to be due in some measure to inclusion in the finished extract of variable amounts of specific tissue protein. A method of preparation and administration of the extract to eliminate reactions is at present under investigation.

This consideration of adequate standards, of adequate dosages, and of reactions substantiates the position taken by the Council on Pharmacy and Chemistry. It is noted with interest that McKhann¹⁰ experimented clinically with the two commercial preparations along with his own extract and its various fractions and obtained similar results with them. In the cases in which commercial products were administered, prevention occurred in 73 per cent and modification in 22 per cent. This further illustrates that adequate dosage for modification without prevention is not clearly defined. (It is not stated that modification was the object in these cases, but in view of McKhann's remarks it seems to be a logical assumption.)

Although this preparation should be of great interest to pediatricians and other physicians, its present status does not seem to warrant general use. It is hoped that additional evidence by those in a position to do adequately controlled clinical work will be forthcoming. This immunizing agent may become a useful measure in combating measles if subsequent results bear out the present evidence. If measles can be adequately and

safely controlled, an advance will have been made against the ravages of a disease the sequelae of which may be more severe than the disease itself, especially in infants

THE PAN-AMERICAN MEDICAL ASSOCIATION

On August 2 the Pan-American Medical Association completed its sixth cruise to South America. The itinerary included brief visits to Nassau, Jamaica and Curaçao, more extended visits to Rio de Janeiro and São Paulo, and again brief visits to Trinidad, Puerto Rico and Bermuda. The visit of more than a hundred American physicians to our South American neighbors must result in benefit to international relations and acquaint the South American countries more fully with the medicine of the United States. Moreover, opportunity was given to the American visitors to obtain an insight into the medical institutions and to some extent into the nature of practice of the countries visited.

The participants in the cruise were cordially greeted and more than welcomed in each of the countries at which the *Queen of Bermuda* called. In all the British territories the governors arranged for official receptions, and in Brazil the president took part in the opening session. Moreover, the participants in the cruise provided for themselves a scientific program that included the presentation of some two hundred manuscripts, motion pictures and graduate lectures. Almost universal satisfaction was expressed by the participants of the cruise in both the scientific and the social functions.

One of the difficulties of a congress of this type is the securing of adequate official representation from the medical professions of each of the nations involved. Dr. Chevalier Jackson, president of the cruise, presented to the organization a gavel containing pieces of wood from each of the twenty-two nations holding membership in the Pan-American Medical Association and expressed the wish that all these nations might be more closely united, as symbolized by the circle of silver enclosing the gavel. Yet on the cruise itself only Chili, Mexico, Brazil, Cuba, Canada and the United States were represented by membership. It might be more conducive to the purposes of the organization if the national medical organization of each of the countries concerned were invited to delegate an official representative for such a congress and if only these representatives were to represent the respective nations on official occasions. Many papers, particularly those on tropical medicine, were contributed by authors who were not themselves present. From the scientific point of view, little is gained by reading such papers in an audience and discussing them in the absence of the authors.

On previous cruises as many as from 400 to 500 physicians have participated. The cruise to Brazil involved five weeks of travel, which no doubt diminished the total number of those taking part to approximately 125 physicians.

The trip more than repaid those who had opportunity to visit the medical institutions of Brazil and Puerto Rico. The Oswaldo Cruz Institute in Rio de Janeiro is one of the finest and best equipped institutions for research in tropical diseases available in the world. The International Health Board occupies a palace formerly used by a mistress of the king of Brazil and there conducts exceedingly interesting work in the prevention and control of yellow fever. The medical school in Rio de Janeiro educates a great number of young men in medicine but on cursory inspection fails to measure up to the class A medical colleges of the United States. Its structure and equipment are lavish, but the ages of the students, the quality of the teaching, and the library and laboratory service are hardly on a par with American standards. The hospitals afford opportunity, however, to see rare conditions not usually seen in the United States and particularly an extensive service in dermatology and the venereal diseases. São Paulo by contrast has a most modern medical school, marvelously equipped through the beneficence of the Rockefeller Foundation. Here the quality of instruction and equipment are excellent. Moreover, there is adjacent to the medical school the Instituto Oscar Freire, a most modern institution for the investigation of legal medicine. This institution provides extensive exhibits in the identification of wounds, stains, hair and similar materials associated with crime; it provides for the study of bullets, fire arms, knives, ropes and other materials used in crime. There are postmortem records covering twenty years, adequately indexed. There is a library of legal medicine and a complete setup for preparation of donors for blood transfusion. Moreover, there is near to São Paulo the Institute of Butantan, an institute of experimental medicine under the direction of Professor Amaral. Here is a complete arrangement for the cultivation of snakes and the preparation of anti-venins. Also special investigations of spotted fever and other tropical disorders are conducted, and the institute provides the usual antitoxins and biologic preparations used in the attack on infectious diseases. So complete is this plant that it raises all the animals used in experimental medicine as well as pedigreed horses and other stock. It provides complete botanic and agricultural setups and a cooperative store and school for all the employees. This institution is also no doubt unique among similar institutions throughout the world.

The Brazilian medical profession received the American tourists with open arms, provided lavishly for their entertainment, and arranged for decorations and diplomas for many of the officers and some of the distinguished members of the cruise.

Many years ago Paracelsus stated his opinion that a physician does not learn by sitting at home behind the stove but by traveling about in other places to see what is being done. The tradition of travel for education in medicine has persisted from the earliest times.

There are trends which indicate to the world the places in which medical education and investigation are advancing, these places thereby become the centers of graduate education. From time to time Germany, Austria, France, Belgium, Alexandria in Egypt, Greece, England, Ireland and various other countries have held their place in the sun. Today many specialties and surgery particularly are studied in the United States. The more frequent interchange of visitors between the United States and the South American countries must result in good for both. For many years the majority of South Americans have gone for education and travel to Europe. A realization by them of what the United States has to offer, a realization by Americans of what the southern half of the American hemisphere has to offer, and the extending of a gesture of friendliness bring about a better understanding not only among physicians but also among all the people of all the American nations.

Current Comment

FROZEN MONKEYS

When the weather gets hot the news gets low, then the newspapers begin to indulge themselves in the vagaries of the pseudoscientists. Thus the big story of last week concerned an experiment said to be performed in California—it would be California—in which a "scientist" claimed to be able to freeze living animals solid and then to restore them to life. The story attracted added attention when volunteers offered themselves for human experiment. Eventually newspapers began to inquire into the antecedents of the "scientist." The records of the American Medical Association indicate that "Dr. Ralph Stanley Willard" is actually not a doctor at all, although he has claimed at various times to have been graduated from Columbia University and from the "Tiflis University College of the City of New York" (?). There seems to be no record of such a school. Indeed, there is no actual evidence that "Dr. Ralph Stanley Willard" was ever in any school of medicine. The records of the American Medical Association reveal the interesting fact that Mr. Willard is presumably a chemist and that in Kansas City in 1927 he was associated with the promotion of the Cunningham tank treatment for many diseases. Moreover, "Dr. Ralph Stanley Willard," who is now called an "obscure Russian scientist," claimed at that time to be actually Prince Raphael Napoleonovitch Lubomirsky and that he was descended from a French marquis who had been left in Moscow by Napoleon. He appeared again in the records in May 1933, when he was convicted in California of violation of the medical practice act and sentenced to spend 150 days and nights in the hoosegow or pay a fine of \$150 and later placed on one year probation. It is perhaps not extraordinary that the newspapers should accept his tales of extraordinary experimentation without any investigation of his status as a scientist or without any certainty that he had actually performed the experiment

reported. There are some investigators who are convinced that the old process known as substitution or sleight of hand was involved in the production of a live monkey in place of the frozen animal, which "Doctor Willard" claims spent three days in the refrigerator. No doubt the volunteer, said to be one Stephen Simkhovitch, a movie writer—it would be a movie writer—will be prevented by the authorities from submitting himself to the congealing process, even though his fiancée has said the experiment is satisfactory to her. Perhaps she likes them cold! But, no doubt, also the California authorities will express themselves with sufficient urgency on the subject to make unnecessary the subsequent trial for murder should the "doctor" proceed with his experiment. According to the newspaper reports, three hundred additional human Californians volunteered themselves for the ordeal. Students of psychology may make their own comments.

MALARIA IN A VILLAGE

An epidemic of malaria recently occurred in a village 30 miles from Cleveland, in which there had not been a case of malaria reported since the health district was organized fifteen years ago. While the evidence as to the original infected person in the outbreak is not complete, some interesting facts are known. A local resident was reported to have had malaria in Florida a few months before returning to this village. On two occasions during the epidemic, however, this person's blood smears were negative for malaria parasites and he lived in a part of town not affected by the epidemic. It seems unlikely that he was the immediate source of the infection. The first person to have malaria in the outbreak was a section hand who had been ill for two months with recurring chills. He lived near a pond in an unscreened shanty near the center of the area affected by the epidemic. A majority of the total of thirty-seven patients lived within a mile of this pond. Hoyt and Worden¹ report that a mosquito survey made at this time showed *Anopheles punctipennis* in abundance along the river which runs by the village. *Anopheles quadrimaculatus*, however, was found in the homes of three malaria patients, and this species of mosquito, it is believed, was the responsible transmitting agent. By oiling the breeding places of mosquitoes and by requiring patients to stay within screened enclosures until four negative blood smears, taken twenty-four hours apart, were obtained, the health commissioner promptly had the outbreak under control. This epidemic probably was not caused by transmission from a local resident. There are many other communities in the United States which are similarly in danger of an outbreak of malaria. They have a pond or swamp where mosquitoes breed and some of them have also the mosquitoes that transmit malaria. When a malaria-infected person visits these communities the stage will be set for an outbreak of malaria. Perhaps a stop in town just long enough to have lunch or to take on motor supplies would be sufficient for the mosquitoes to find the malaria-infected visitor.

¹ Hoyt, R. N. and Worden, R. D. *Malaria Epidemic in Aurora, Ohio*. Pub. Health Rep. 50: 895 (July 5) 1935.

Association News

BRITISH PHYSICIANS VISIT UNITED STATES EN ROUTE TO AUSTRALIA

Fifty-five British physicians, with members of their families making a group of 110, visited New York, Washington, Chicago, Albuquerque, the Grand Canyon, Los Angeles and San Francisco between August 4 and 14 on their way to the annual session of the British Medical Association in Melbourne, Australia, in September. On their arrival in New York on the *S S Georgic* Sunday, August 4, the visitors were met by Drs Morris Fishbein and Austin A Hayden, Chicago, and Arthur W Booth Elmira N Y, representing the American Medical Association, and by Drs Frederic E Sondern, New York, and Arthur J Bedell, Albany, president and immediate past president, respectively, of the Medical Society of the State of New York. Sunday afternoon the guests were taken by motor to Grasslands Hospital, Valhalla, N Y, with a special police escort. Monday, August 5, was spent in visits to the Columbia University-Presbyterian Hospital Medical Center, the New York Hospital-Cornell Medical Center, the Rockefeller Institute for Medical Research and other points of interest, with a luncheon at the Waldorf-Astoria. The following two days, Tuesday and Wednesday, the party saw the sights of Washington, D C, and Mount Vernon. They were received at the White House and entertained at a reception at the British embassy. They were also guests at a luncheon at the Mayflower Hotel, at which officials of the Army and Navy medical corps the U S Public Health Service, the British embassy and the Medical Society of the District of Columbia were hosts. Arriving in Chicago, August 8, the British visitors spent the day viewing places of interest in the city accompanied by Dr Hayden, who was in charge of arrangements for the day, Dr Olin West, Secretary of the American Medical Association, Dr Fishbein, Dr Thomas P Foley, president-elect, and Dr Robert Hayes, secretary of the Chicago Medical Society, and Dr Lemuel E Day, member of the council of the Illinois State Medical Society. At the Union Stockyards Mr G H Swift, together with medical and other officials of the firms of Swift and Company, Armour and Company and Libby, McNeill and Libby were hosts at a luncheon for the visitors. At a tea at the Edgewater Beach Hotel Mr Robert Ross, acting British consul in Chicago, and representatives of the various official bodies made addresses, to which Dr Ernest Kaye Le Fleming, chairman of the council of the British association responded. In the evening the party was entertained at dinner at the Stevens Hotel, during which there was cabaret entertainment, later individual members of the group were guests at private parties. During the day Prof Ernest W Hey Groves operated at Cook County Hospital. Sir Comyns Berkeley, Sir Ewen MacLean and Prof John Bright Banister visited the radium centers at Michael Reese Hospital and the Chicago Lying-In Hospital.

At midnight they departed on a special train for Albuquerque, N M, where they were to be entertained by the Bernalillo County Medical Society, Saturday, August 10, with visits to the University of New Mexico and the Indian village of Isleta. The next day was spent at the Grand Canyon as guests of the local medical society. Thence the British physicians were to go to Los Angeles for the day and night of August 12, with the Los Angeles County Medical Association as hosts. Tuesday, August 13, they were to take the daylight coast line trip to San Francisco, where the San Francisco County Medical Society and the California Medical Association were to entertain them with sightseeing and a luncheon at the Palace Hotel. In the afternoon they were scheduled to embark on the *S S Aorangi* for Australia, stopping one day at Honolulu, where the Hawaiian Territorial Medical Association and the Honolulu County Medical Society have planned entertainment including sightseeing trips around the island of Oahu and a dinner at the Royal Hawaiian Hotel, with special Hawaiian music and dancing, if time is available before the boat sails.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

ALABAMA

Increase in Malaria—An appropriation of \$1,967,980 has recently been approved by President Roosevelt to finance a drainage program in all counties of Alabama for the control of malaria. Reports indicate an alarming increase in the disease, despite the elaborate program of malaria control carried out in the state last year, 1,132 cases having been recorded during the first five months of 1935 as compared with 514 for the similar period in 1934. This is the first time in ten years that so much malaria has been reported for a corresponding period, it is said.

State Health Conference—All city and county health workers in the state met in Montgomery, July 22-23, for a conference called by the state health officer, Dr James N Baker. Governor Graves opened the meeting and speakers included

Dr Calvin C Applewhite, U S Public Health Service, Training of Personnel
Dr Daniel C Gill, Montgomery Tuberculosis and Hookworm.
Mr G H Hazlehurst, Montgomery Malaria Control and Sanitation.
Dr Burton F Austin, Montgomery Maternal Infant and Child Hygiene.

CALIFORNIA

Dr Porter's Term Extended—At a recent meeting of the board of regents in Los Angeles, the term of Dr Langley Porter as dean of the University of California Medical School San Francisco, was continued one year. Dr Porter's normal retirement period was reached this year, it was stated. He has been dean of the medical school since 1927.

Graduate Courses—The Stanford University School of Medicine in cooperation with the San Francisco Department of Public Health will conduct a series of graduate courses for practicing physicians, September 10-13. Morning lectures will review cardiology, diseases of the chest and obstetrics and gynecology, while afternoons will be devoted to medical aspects of syphilis and its treatment, proctology, surgical anatomy with special reference to operative approach and technique, and ophthalmology. The first evening session will be given over to a consideration of nephritis and hypertension, the second to glandular diseases and their treatment, and the third to gastrointestinal disease.

COLORADO

Hospital News—An appropriation of \$691,700 has been allotted to the Fort Lyon Veterans' Hospital by the Veterans' Administration, for additions.

State Board Election—At a special meeting of the Colorado State Board of Medical Examiners, Denver, recently, Drs Vardry A Hutton, Florence, was chosen president, Nohe Mumey, Denver, vice president, and Harvey W Snyder, Denver, secretary-treasurer.

Radiologic Conference—The Denver Radiological Club will hold a midsummer radiologic conference, August 28-30. The program will comprise symposiums on neoplastic diseases, development, anomalies and diseases of the spine, and pulmonary and gastro-intestinal diseases. Speakers will include Drs. Benjamin H Orndoff, Chicago, secretary of the American College of Radiology, William Edward Chamberlain, Philadelphia, professor of radiology and roentgenology, Temple University School of Medicine, James M Martin, Dallas, Texas, professor of radiology, Baylor University School of Medicine, and Dr Henry J Ullmann, Santa Barbara, Calif. In addition, local physicians on the program include Frederick E. Diemer, president of the Denver Radiological Club, Sanford M. Withers, Harry S Finney, Josiah N Hall, Ernst A Schmidt, Henry Sewall, Luther R. Moore, Leonard G Crosby, Samuel B Childs, Kenneth D A Allen, William W Wasson, Hamilton I Barnard, Frank B Stephenson and John S Bouslog, all of whom are from Denver. A joint meeting will be held with the Medical Society of the City and County of Denver, August 28, at which Drs Chamberlain and Ullmann will be the speakers. Dr Harmon P Brandenburg, Denver, will address the banquet.

DISTRICT OF COLUMBIA

Medical Bills in Congress—H. R. 8552, introduced by Representative Smith, Virginia, proposes to direct the Commission on Licensure to Practice the Healing Art in the District of Columbia to issue a license to practice the healing art in the District of Columbia to Dr. Leo Solet.

GEORGIA

Glynn County Wins Prize—Dr. Millard E. Winchester, Brunswick, commissioner of health of Glynn County, was guest of honor at a dinner given by the Brunswick Board of Trade, June 28, in recognition of his county's winning first prize in the southeastern division of his county's winning first prize in this year by the U. S. Public Health Service and the Chamber of Commerce of the United States. A plaque has already been presented to the county, commemorating the accomplishments in health conservation for 1934. Speakers at the dinner included Dr. Thomas F. Abercrombie, director of public health, who served as the first health officer of Glynn County. This county was the first in the state to have the services of a paid health officer.

Society News—Dr. Robert B. McIver, Jacksonville, Fla., was chosen president of the Chattahoochee Valley Medical Association at its annual meeting at Radium Springs, near Albany, July 9-11. Other officers elected are Drs. John C. Keaton, Albany, and Edward S. Sledge, Mobile, Ala., vice presidents, and Frank K. Boland, Atlanta, secretary-treasurer. The next annual session will be at Radium Springs. Included on the program were the following physicians:

- David Henry Poer, Atlanta: Carcinoma of the Thyroid
- Thomas L. Ross Jr., Macon: Peripheral Vascular Disease with Special Reference to the Lower Extremities
- Willis P. Jordan, Columbus: Urologic Disorders Undiscovered in Physical Examinations
- Frank K. Boland, Atlanta: Surgical Treatment of Pulmonary Tuberculosis
- Roy R. Kracke, Emory University: Agranulocytosis Etiology, Diagnosis and Treatment
- Harold P. McDonald, Atlanta: Suction of Undescended Testicle

The William J. Love Lectureship was created at this meeting in honor of the late Dr. Love, Opelika, who had been secretary of the association since its organization.

ILLINOIS

Tests for Skill of Drivers at State Fair—Medical examination of adults for heart impairment and tests to determine the skill of automobile drivers will be offered free to all visitors to the state fair in Springfield August 17-23, as special features of the exhibits on health and safety, according to the state health department. Each person who takes the test will receive a record showing his reaction time and folder indicating a safe speed for him together with driving rules. The Sangamon County Medical Society is cooperating in the heart examinations, and Dr. John J. McShane, chief of the state division of communicable diseases, will be in charge.

Gastro-Enteritis Due to Contaminated Milk—More than twenty cases of gastro-enteritis at Enfield recently were traced to a contaminated raw milk supply, the state health department reports. The milk from three cows was served to the members of a women's missionary society. Some of the milk was given to friends in the community and the remainder was used by the family. Within four hours after drinking the milk fourteen of the twenty society members, four of the family members and several friends were seized with paroxysms of vomiting followed by diarrhea. Tests showed the milk to be heavily infected with staphylococci. The outbreak subsided when use of the milk was discontinued.

IOWA

Rocky Mountain Spotted Fever—Four cases of Rocky Mountain spotted fever have been reported to the state health department thus far in 1935 including one death (THE JOURNAL, July 27, p. 287). The counties involved, Linn, Lee, Poweshiek and Union, are widely separated in the southern half of the state. The death was that of a little girl in Linn County.

KANSAS

Society News—At a joint meeting of the Brown County Medical Society and the newly organized Northeast Kansas Dental Association in Hiawatha, June 28, speakers were Dr. Charles L. Husted, Falls City, on 'Management of Post-operative Complications,' and Mr. A. L. Peterson, Topeka, on 'Medical Dental Jurisprudence.' Dr. Robert M. Brian, El Dorado, among others, addressed the Butler-Greenwood County Medical Society in El Dorado on Encephalitis Lethargica.

Its Complications and Sequelae.—Dr. Robert L. Ferguson, Arkansas City, discussed medical care of the indigent before the Cowley County Medical Society in Arkansas City, June 20. At a meeting of the Crawford County Medical Society in Pittsburg, June 27, Dr. Roletta O. Jolly-Fritz spoke on dementia praecox. Papers were presented before the Dickinson County Medical Society in Hope, July 18, by Drs. Lawrence G. Heins, Abilene, and Theodore Kroesch, Enterprise, on "Diseases of the Coronary Arteries" and "State Medicine," respectively. The Golden Belt Medical Society was addressed at its quarterly meeting in Manhattan, July 11, by Drs. Walter M. Reitzel, Manhattan, on "Bladder Neck Obstructions," Emmanuel Raymond Gelvin, Concordia, "Transurethral Prostatectomy, Its Progress and Possibilities," Ray M. Balyeat, Oklahoma City, "Therapeutic Value of the Intratracheal Use of Iodized Oil in the Treatment of Intractable Asthma," and Allen B. Kanavel, Chicago, "Diagnosis and Treatment of Infections of the Hand."

LOUISIANA

Personal—The completion of thirty-five years' practice in Gretna by Dr. Charles F. Gelbke was observed with a reception recently held by his friends in Jefferson Parish. Among other gifts, he received a bronze statue and an automobile. Dr. Gelbke has served as mayor of Gretna and coroner of the parish. Dr. Bjarne Pearson, Taylors Falls, Minn., has been appointed assistant professor of pathology at the Louisiana State University Medical Center, New Orleans.

Dr. Matas Resigns from Touro Infirmary—Dr. Rudolph Matas has resigned as chief of the department of surgery at Touro Infirmary, New Orleans, and Dr. Isidore Cohn has been appointed to succeed him. It was stated that Dr. Matas wished "to free himself of administrative and teaching duties so that he would have more time to devote to strictly professional activities." Following his resignation, Dr. Matas was named honorary chief of the surgical service at the infirmary. A native of New Orleans, Dr. Matas was named as the school of Medicine in 1880. He was professor of surgery at Tulane from 1895 until 1927. He has been chief senior surgeon at Touro Infirmary since 1905. Dr. Matas was vice president of the American Medical Association in 1921 and again in 1932. Last year the Violet Hart Fund established a medal in his honor at Tulane University to be awarded to the "North American surgeon who has contributed outstanding work in vascular surgery." In 1926 Dr. Matas was presented with the Henry Jacob Bigelow Medal of the Boston Surgical Society in his fiftieth anniversary in the practice of medicine and marking his fiftieth anniversary in the practice of medicine a festschrift was published in his honor, containing contributions of professional friends and colleagues. Dr. Cohn is clinical professor of surgery at Tulane and professor of surgery at the graduate school and has been associated with Dr. Matas at Touro Infirmary for many years. He is 50 years of age and graduated from Tulane in 1907.

MINNESOTA

Physicians' Hobby Exhibit—An extensive display of physicians' hobbies was a feature of the recent annual meeting of the Minnesota State Medical Association in Minneapolis, June 24-26. Grouped under the following headings, exhibits included:

- Anecdotes and Epigrams: Dr. Charles G. Sutherland, Rochester, Minn.
- Archery: Drs. John M. Armstrong, St. Paul, and Austin V. Denman, Mankato.
- Architectural Drawings: Dr. Leo M. Crafts, Minneapolis.
- Big Game: Drs. Kenneth Bulkley and Frederick H. K. Schaaf, Minneapolis.
- Minneapolis: Austin V. Denman and John T. Schlesselman, Mankato.
- Edmund L. Warren, St. Paul.
- Birds: Dr. Thomas S. Roberts, Minneapolis.
- Boats: Drs. Armstrong and Gilbert G. Cottam, Minneapolis.
- Books: Dr. Richard O. Leavenworth, St. Paul.
- Charcoal Sketches: Dr. David L. Tilderquist, Duluth.
- Clay Models: L. B. Franklin, student, University of Minnesota.
- Medical School Drawings: Dr. Frederick A. Willius, Rochester.
- Feeding Bottles: Dr. Robert Rosenthal, St. Paul.
- Guns: Drs. Bulkley, Paul F. Dwan, Schaaf, Louis B. Wilson, Rochester.
- Crafts: Dr. John S. Holbrook, Mankato.
- Oil Paintings: Drs. Russell T. Costello, Rochester, Arthur N. Collins, Duluth, Schlesselman and Luisa Herschbaumer, St. Peter.
- Photographs: Drs. Walter C. Alvarez, Rochester, Horace G. Scott, Arthur T. Henri, Erling S. Platou, Minneapolis, Eric P. Quam, Bemarek, N. D.
- Stamp Collection: Dr. Carlos W. del Plaine, Minneapolis.
- Miscellaneous: Drs. Bulkley, Schaaf, Richard O. Leavenworth, and Edmund L. Warren, St. Paul, Gordon B. New, Rochester.
- Music: Dr. Virgil J. Schwartz, Minneapolis.

The Minneapolis Rifle Club also furnished an exhibit, physicians members were Drs. Frederick A. Olson and Arthur C. Skjold. Several dentists also participated in the hobby show.

MONTANA

Society News—Dr George E. Brown, Rochester, Minn., addressed physicians of Great Falls and vicinity, July 3, on cardiovascular diseases

NEBRASKA

Personal—Dr Francis W. Heagey, Omaha, was elected president of the Nebraska Tuberculosis Association at the recent annual meeting—Dr Victor E. Levine, professor of biological chemistry and nutrition, Creighton University School of Medicine Omaha, is in Alaska continuing his studies of the Eskimo. He will make observations in the region north of Nome including Teller Cape Prince of Wales, Deering, Kivalik, Shishmaref Kotzebue Point Hope, Point Lay, Wainwright and Point Barrow. This is Dr Levine's third trip to the arctic

NEW MEXICO

Position Open for Health Officer—Dr J. Rosslyn Earp, state health officer, announces that an examination to qualify for the position of district health officer will be held at Santa Fe, September 7. Dr Owen E. Puckett, Carlsbad has been appointed health officer of a district made up of Eddy, Lea and Chaves counties

NEW YORK

Hospital News—Dr Clarence H. Bellinger, assistant superintendent at Utica State Hospital Utica, has been appointed superintendent of the Brooklyn State Hospital. He will succeed Dr George W. Mills who will become superintendent of the Creedmor State Hospital, formerly a division of the Brooklyn institution but recently made separate by legislative enactment

Typhoid Carriers—Thirty-nine chronic typhoid carriers were discovered during 1934 by the New York State Department of Health, making a total of 335 in the state, exclusive of New York City, where there were 352 and state institutions, in which there were fifteen. Twenty-two of the newly discovered carriers were housewives, seven were in the milk industry, one was a hotel cook and nine were in occupations not connected with food. All were more than 20 years old, the oldest 78

New York City

Hospital News—A new private pavilion with a capacity of seventy-five beds is to be built at Columbus Hospital Extension at a cost of \$170,000—Dr Kurt Goldstein, formerly of Frankfurt and Berlin, Germany has been appointed attending physician on the neurologic division of Montefiore Hospital and will be in charge of a new neuropsychologic laboratory

Regulations on Sale of Vitamin D Milk—In order that consumers may know what kind of vitamin D milk they are receiving, the department of health has recently issued regulations requiring complete information to be printed on the caps of bottles. This must include not only the method that has been used in fortifying the milk but also the number of units of vitamin D per quart. The board has fixed the following minimum vitamin D content for the three kinds if produced by feeding irradiated yeast to cows, 430 units per quart if produced by direct irradiation with ultraviolet rays or carbon arc ray lamps 135 units if produced by the addition of concentrate, 400 units. Physicians should give instructions as to which kind of vitamin D milk they wish their patients to receive, the health department bulletin suggested

OHIO

Personal—Dr Charles O. Munns Oxford, was guest of honor at a meeting of the Oxford Kiwanis Club, July 23 celebrating his completion of fifty years of medical practice—Dr J. Will Payne, Willowood, has been appointed health officer of Lawrence County—Dr Gail E. Miller, Lima has been named health officer of Allen County on a part time basis to succeed Dr John J. Sutter, who served sixteen years as a full time officer—Dr Howard Dittrich, Cleveland, has been named an official delegate from the United States to the Tenth International Congress of the History of Medicine in Madrid, September 23-29. He will read a paper on 'Early American Devices for Infant Feeding'

Society News—Speakers at a meeting of the Adams County Medical Society, West Union June 26 were Drs William B. Morrison and Frank W. Harrah, Columbus, on "Surgical Treatment of Lesions of the Gastro-Intestinal Tract" and Transurethral Resection of the Prostate, respectively, and Samuel C. Clark, Cherry Fork. Mumps—Dr John A. Caldwell Jr., Cincinnati, addressed the Butler County Medical

Society, Hamilton, June 12, on "Acute Traumatic Bone Atrophy"—Dr Joseph D. Heiman, Cincinnati, addressed the Clinton County Medical Society, Blanchester, on "Uterine Bleeding"—At a meeting of the Highland County Medical Society, Hillsboro, June 5, Dr Wells H. Teachnor Jr., Columbus, spoke on 'Mesenteric Adenitis'—Dr Forest William Cox, Dayton, was guest speaker at a meeting of the Greene County Medical Society, Xenia, July 3 on 'Common Diseases of the Lower Third of the Colon'—Drs Eugene F. McCampbell and Sylvester J. Goodman, Columbus, addressed the Auglaize County Medical Society, Minster, June 27, on "Heart Disease in Pregnancy" and 'Common Toxemias of Pregnancy,' respectively—Dr Milton B. Cohen, Cleveland, addressed the Trumbull County Medical Society, Warren, June 19, on 'Allergic Influences on Diseases'—Drs Samuel L. Meltzer, Portsmouth, discussed x-ray and radium treatment of cancer at a meeting of the Hempstead Academy of Medicine, Portsmouth July 8—Dr Charles A. Doan, Columbus, addressed the Tuscarawas County Medical Society, Uhrichsville, July 11, on anemia

PENNSYLVANIA

Symposium on Endocrinology—The Montour County Medical Society sponsored a symposium on the thyroid gland and the endocrine system at the Geisinger Memorial Hospital, Danville July 25. Dr Harold L. Foss conducted an operative clinic in the morning and Dr Richard B. Cattell, Boston, a dry clinic in the afternoon. The following program of papers was presented

Dr Henry F. Hunt, Danville, Pathology of the Thyroid Gland.
Dr Carl E. Ervin, Danville, The Heart in Hyperthyroidism.
Dr Cattell, Hyperthyroidism—Its Diagnosis and Treatment.
Dr George M. Curtis, Columbus Ohio, Significance of the Iodine Content of Human Blood.
Edward C. Kendall, Sc.D., Rochester, Minn., Historical Outline of Treatment of Exophthalmic Goiter.
Prophylactic Use of Iodine.
Production of Goiter Through Administration of Organic Iodides.
Recent Work on the Thyrotropic Hormone: Relation Between the Thyroid and Suprarenal Glands

RHODE ISLAND

Medicolegal Society Fifty Years Old—The Rhode Island Medico-Legal Society celebrated its fiftieth anniversary at a dinner at the Narragansett Hotel, June 27. Speakers were Dr Fritz W. Gay, Malden, president, Massachusetts Medico-Legal Society, Dr Timothy Leary, Boston, medical examiner of Suffolk County and Charles A. Walsh, associate justice of the Superior Court of Rhode Island. Officers elected were Dr Benjamin F. Tefft, West Warwick, president, Sigmund W. Fisher Jr., Providence, vice president, and Dr Jacob S. Kelley, Providence, secretary

TENNESSEE

Rockefeller Gift to Vanderbilt University—The General Education Board, New York, has made a gift of \$2,500,000 to Vanderbilt University for the school of medicine, it was announced July 1. About \$700,000 will be used for buildings and equipment and the remainder for an endowment, it was said.

University News—A portrait of the late Dr. William B. Rogers at one time dean and professor at Memphis Hospital Medical College was presented to the University of Tennessee College of Medicine June 4, by former students and faculty of the old college. The presentation was made by Dr Joseph A. Crisler Sr at a meeting of the Memphis and Shelby County Medical Society and was accepted by Dr James B. McElroy, professor of medicine. At the society meeting Dr Giles A. Coors presented a paper on enterostomy

WEST VIRGINIA

Society News—Drs Arthur A. Shawkey and Randolph L. Anderson Charleston addressed the Fayette County Medical Society, Oak Hill, July 16, on 'Pyelonephritis in Infancy and Childhood and Injuries of the Spinal Column, Old and New' respectively—A symposium on cancer was presented before the Central West Virginia Medical Society in Webster Springs, July 27, by Drs Rome H. Walker, Benjamin H. Swint, McLeod Gilhes, John E. Cannaday and J. Ross Hunter, all of Charleston—Dr John W. Strieder, Ann Arbor, Mich., addressed a joint meeting of the Preston and Monongalia County medical societies at Hopemont Sanitarium, July 9, on 'Surgical Treatment of Pulmonary Tuberculosis'

WISCONSIN

Scarlet Fever Declines—For the first time in two years a day passed without a new case of scarlet fever in Milwaukee, the health department reported July 25. The total number of active cases was sixty one, as compared with 233 a year before and 1,513 February 1

HAWAII

Cancer Survey—Dr John M Flude, western field representative of the American Society for the Control of Cancer, has recently completed a cancer survey in the Hawaiian Islands. The Territorial Medical Society sponsored the survey, a report of which is not yet available.

GENERAL

Orthopedic Board Examination—The American Board of Orthopedic Surgery announces that its next examination will be held in St Louis in January 1936. Candidates interested in the activities of the board may obtain information by writing the secretary, Dr Fremont A Chandler, 180 North Michigan Avenue, Chicago. This board was incorporated in 1934 and has been approved by the Advisory Board for Medical Specialties. Besides Dr Chandler, officers are Drs Melvin S Henderson, Rochester, Minn., president, Edwin W Ryerson, Chicago, vice president, and Henry W Meyerding, Rochester, Minn., treasurer.

Medical Bills in Congress—Changes in Status The conference report on H R 7260, the social security act, has been approved by the House and Senate. H R 8554, the Second Deficiency Appropriation Bill, has been sent to the President for his approval. This bill appropriates \$21,250,000 for veterans' hospital and domiciliary facilities. H R 4513 has passed the House, authorizing the payment of claims for unauthorized emergency treatment of World War veterans. **Bills Introduced** H R 9010, introduced by Representative Cartwright, Oklahoma, proposes to authorize an appropriation of \$250,000 for the construction of a hospital for Indians at Tahina, Le Flore County, Oklahoma.

Bacteriologists Organize Branch Society—The North Central Branch of the Society of American Bacteriologists was organized during the meeting of the American Association for the Advancement of Science at the University of Minnesota, Minneapolis, June 26, with Robert E Buchanan Ph D, dean of the graduate college and director of the agricultural experiment station, Iowa State College, Ames, Iowa, as president, Dr Arthur T Henrici, professor of bacteriology and immunology, University of Minnesota Medical School, vice president, and Rudger H Walker, Ph D, Ames, secretary. The branch society includes members of the national organization and others living in Minnesota, Wisconsin and Iowa. Semiannual meetings will be held, rotating between Minneapolis, Madison and Ames. Included on the program were the following:

Halvor O Halvorson Ph D University of Minnesota The Effect of Chance on the Mortality of Experimentally Infected Animals
Dr Robert G Green University of Minnesota The Nature of Filtrable Viruses
Dr Edward C Rosenow Rochester Minn Studies on Experimental Encephalitis and Poliomyelitis
Clifford P Fitch Sc D, and Lucille Bishop, University of Minnesota, A Study of Certain Methods for the Isolation of Brucella Abortus from Milk

Medical Papers at Chemists' Meeting—At the summer meeting of the American Chemical Society in San Francisco, August 19-22, the following papers, among others, will be presented in the division of medicinal chemistry:

Dr Paul J Hanzlik and Arthur P Richardson San Francisco, State of Bismuth in Body Fluids and Tissues
Drs Jacob Arnold Bergen and Bayard T Horton and Arnold E Osterberg Ph D Rochester Minn, Lead in the Chemotherapy of Cancer
Dr Maurice L Tainter, San Francisco, The Role of Chemical Structure in the Activity of Diotrophenol Derivatives as Metabolic Stimulants
Dr Francis M Pottenger Jr, Monrovia, Calif Clinical and Experimental Observations of the Effects of Suprarenal Hormones
Dr Howard L Eder, Santa Barbara Calif Use of Iron Therapy by the Normal Individual for the Prevention of Sunburn
Margaret Cammack Smith Tucson Ariz. Relation of Diet to Fluorine Toxicities
Dr Herbert M Evans, Oliver H Emerson Ph D and George A Emerson Berkeley Crystalline Derivatives of an Alcohol Having Vitamin E Potency
Chauncey D Leake Ph D San Francisco Pharmacologic Aspects of Vitamins

Joint symposiums will be held with the divisions of agricultural and food and biological chemistry, of which some of the papers mentioned will form a part.

Anniversary of Narcotics Limitation Convention—Secretary of State Cordell Hull in a message to the World Narcotic Defense Association at a luncheon in New York, July 9, said that cooperation by the United States with other nations in suppression of the abuse of narcotic drugs is handicapped by the inadequacy of state laws. The luncheon was held to celebrate the second anniversary of the coming into effect of the Narcotics Limitation Convention of 1931. Fifty-four governments have ratified or acceded to the convention of 1931 and fifty-nine are parties to the Hague Opium Convention of 1912, Secretary Hull reported, there are only eight

governments that participate in none of the narcotic drug conventions. To make the international agreements effective, enactment of state laws is necessary, the federal government has done all it can to meet the treaty obligations, Secretary Hull said. More than half the states have already enacted the uniform state narcotic drugs act, which is designed to fulfill the treaty obligations. Among these obligations Secretary Hull named control of the production and distribution of raw opium, limitation of the manufacture, sale, distribution and use of narcotics to medical and scientific purposes, control of the production of cannabis sativa, and restriction of the manufacture of narcotic drugs to persons, establishments and premises licensed for the purpose.

Congress of Physical Therapy—The fourteenth annual session of the American Congress of Physical Therapy will be held in Kansas City September 9-12, with headquarters at the Hotel Kansas Citian. An instruction course under a corps of twenty lecturers will precede the meeting, September 5-7. The formal opening of the congress will be Monday evening, September 9, when Dr John S Hibben, Pasadena, Calif, will be installed as president. Dr Arthur Steindler, Iowa City, will deliver the third annual William Benham Snow lecture, on "Physical Properties of Bone." Section meetings will be held Tuesday and Wednesday mornings and the remainder of the time will be devoted to general assemblies. Among speakers on the general program are:

Dr Ralph H Kuhns, Chicago, Present Status of Fever Therapy for Dementia Paralytica in the State Hospitals of Illinois
Dr Vernon L Hart, Minneapolis Mechanical and Physiologic Principles Underlying Prevention of Deformity and Disability
Dr Theodore P Brookes, St Louis, Hallux Valgus Postoperative Physical Therapy
Dr Lester Hollander Pittsburgh, Treatment of Cancer of the Lip by Massive Doses
Dr Edward H Skinner, Kansas City Radium Therapy in the Curable Field of Malignancy
Dr Lewis J Moorman, Oklahoma City Intrapleural Pneumolysis
Dr Miland E Knapp Minneapolis, Treatment of Erysipelas by Ultra violet Radiation

Included in the program will be symposiums on electrosurgical resection of the prostate, short wave diathermy, arthritis and gynecology. Tuesday evening there will be a joint meeting with the Jackson County Medical Society, with the following speakers: Drs Bernard Fantus, Chicago, on "Unemployability: A Medical Problem", Franz Nagelschmidt, London, "Present Status of Physical Medicine in Treatment of Disease" and Henry W Meyerding, Rochester, Minn., "Volkmann's Ischemic Contracture."

Boy Scout Jamboree Canceled Because of Poliomyelitis—In a statement from the White House, August 8, President Roosevelt canceled the International Boy Scout Jamboree, which was to have been held in Washington, August 19-30, because of the outbreak of poliomyelitis in Virginia within 100 miles of the capital. Thirty thousand boys from all parts of the world were to have come to Washington. The decision was made after a conference with Surg Gen Hugh S Cumming of the U S Public Health Service Commissioner George Allen of the District of Columbia and James E. West, New York, chief scout executive. While the prevalence of the disease was not "unduly alarming," it was thought better not to create undue apprehension on the part of parents and of state health officers, who might fear that the disease would be brought back by returning scouts. The poliomyelitis epidemic was believed to be declining in North Carolina, where it first appeared only thirty-seven cases having been reported from August 1 to 7. From May 1 to August 1 there were 468 cases. The outbreak appeared later in Virginia, only fifty-two cases having been reported in June as compared with 198 in North Carolina. In July, however, Virginia had 250 and North Carolina 226. From August 1 to 7 the number of cases reported in Virginia was ninety-one. It was said that the epidemic area was apparently not extending except for a slow northward spread. Dr Alexander G Gilliam of the U S Public Health Service was transferred to Virginia, July 20, after spending several weeks in North Carolina in connection with the outbreak. Midshipmen of the U S Naval Academy, Annapolis, Md, have been ordered not to go to North Carolina and Virginia during their annual leave from August 30 to September 27. Thirty cases were reported to the state health department of Tennessee during July, according to the Nashville Tennessean, July 31, a number definitely above the normal expectation. Most of these were in counties of East Tennessee near the North Carolina and Virginia borders, twelve occurred in Stewart County in the western part of the state. The Delaware State Board of Health has adopted the procedure of requiring all persons from the poliomyelitis area to register with the nearest health unit and to be examined daily for twelve days.

Government Services

Changes in Public Health Service

Passed Asst Surg Adolph S Rumreich, relieved at Washington, D C, and assigned at Moscow U S S R
 Passed Asst Surg Edward C Rinck relieved at Norfolk Va, and assigned at Washington
 Passed Asst Surg Thomas B McKenely relieved at Washington and assigned at the marine hospital Ellis Island
 Sr Surg Newton E Wayson, relieved at Honolulu and assigned at the marine hospital, Baltimore
 Surg Lueius F Badger, relieved at Washington and assigned at Honolulu in charge of the leprosy investigation station
 Medical Director Ernest A Sweet relieved at Ellis Island and assigned in charge of the quarantine station at Gallops Island Boston
 Sr Surg Harry F White, relieved at Curtis Bay Baltimore, and assigned at Port Townsend in charge of quarantine station
 Surg LeGrand B Byington relieved at Angel Island and assigned in charge of quarantine station at Curtis Bay Baltimore
 Asst Surg John W Oliphant relieved at Seattle and assigned at marine hospital in Chicago
 Asst Surg Frederiek J Brady relieved at marine hospital, Chicago and assigned at marine hospital Seattle
 Passed Asst Surg Mason V Hargett relieved at Warsaw Poland and assigned at Stuttgart

Position Open in Indian Medical Service

The U S Civil Service Commission announces an open competitive examination for the position of area medical director in the Indian Service, Department of the Interior, at a salary of \$5,600 a year. Applications must be filed with the commission at Washington, D C, not later than August 26. At present there is a vacancy in the consolidated Navajo area and it is possible that similar positions will be created in the near future, according to the announcement. Competitors will not be required to report for examination but will be rated on education and experience. They must be citizens of the United States and graduates of recognized medical schools. In addition they must have had at least three years' experience in the fields of medicine and public health among peoples whose concepts of medical science are primitive. They must have had two years of responsible paid full-time administrative experience in a state or national organization of recognized influence devoted to promoting public health. A degree of doctor of public health from a recognized university may be substituted for one year of this experience. They must not have reached their fifty-third birthday. Further details and application forms may be obtained at any first class postoffice, from the commission at Washington, D C, or from the civil service district office in any of the following cities: Atlanta, Boston, Chicago, Denver, New Orleans, New York, Philadelphia, Seattle, St. Louis, St. Paul, San Francisco, Honolulu, Balboa Heights, C Z, and San Juan, P R.

New Units for Food and Drug Research

Two new divisions have been organized in the Food and Drug Administration of the U S Department of Agriculture to conduct research on vitamins and in pharmacology, it is announced. The vitamin division will be under the direction of Elmer M Nelson, Ph D, recently associated with the Bureau of Chemistry and Soils. Its work will be to check the claims and help establish standards for food and drugs for which claims of vitamin potency are made. Chester D Tolle Ph D, who has engaged in research on vitamin potency with the U S Bureau of Fisheries, has also been appointed to Dr Nelson's staff. The pharmacologic division is headed by Dr Erwin E Nelson, associate professor of pharmacology of the University of Michigan Medical School, Ann Arbor, who was appointed principal pharmacologist of the Food and Drug Administration last January. Dr Nelson is on leave of absence from the university until the beginning of the academic year 1936-1937. In addition to the original staff of the pharmacologic section, the following have been newly appointed: Dr Edward W Wallace, from the University of Chicago, Dr George E Farrar Jr, University of Michigan, Ann Arbor, Lloyd C Miller, Ph D, recently with the University of Rochester, N Y, J M Curtis, Ph D, National Research Fellow in Anatomy at Yale University, New Haven, during the past year, Herbert O Calvery, Ph D, assistant professor of physiologic chemistry, University of Michigan, Ann Arbor, and Edwin P Laug, Ph D, University of Pennsylvania. It will be the duty of this division to develop methods for identification and evaluation of new types of medicinal preparations such as glandular extracts, to study effects of substances known to occur as impurities, such as arsenic and lead, to study toxicity of insecticides used as sprays on fruits and vegetables, and to learn the effects of new synthetic products according to a statement made by Walter G Campbell, chief of the Food and Drug Administration.

Résumé of the Public Health

In the house of commons Sir Kingsley Wood, minister of health, surveyed the progress of public health in the last twenty five years. He said that never during a single generation had there been such advances in the preservation of life and the improvement of health of our people. Above all there had been a great widening of the national conscience on the matter of health. The nation was learning in many ways the supreme art of right living, was showing greater common sense in health, clothing and the dietary, and was making increasing use of daylight for leisure and recreation. Life was becoming longer and better. In 1910 the death rate at all ages was 13.5 per thousand persons, and 95,000 infants under the age of 1 year died. Last year the death rate had fallen to 11.8 and the deaths of infants to 35,000, yielding the lowest rate on record. Cancer accounted for 60,000 deaths last year, but he had hopes from research and the increasing use of radium.

National health insurance had developed during the last quarter of a century. Since 1911, \$2,400,000,000 had been disbursed in benefits and in the last ten years \$750,000,000. That scheme had been adopted by twelve other nations, from Norway to Japan. Widows and old age pensions had steadily expanded and now included 600,000 pensioners between the ages of 65 and 70, 600,000 widows' pensions supplemented by 270,000 allowances in respect of children, and 15,000 orphans' pensions.

Unreduced maternal mortality was a great blot on the health record. It was a complex problem requiring patience, constant research and active endeavor. A committee that inquired into 6,000 maternal deaths reported that 3,000 might have been prevented. In the past three years there had been an increase in the visits paid by health visitors to 60,000 expectant mothers, 240 more antepartum clinics had been provided, and the number of women attending had increased by 49,000. The number of women admitted into maternity beds provided by the local authorities or subsidized by them had increased by 29,000. He had great hopes in the special inquiries into maternal mortality that were being made by his officers with the assistance of a distinguished specialist.

Slum clearance and better housing was one of the greatest contributions of this generation to making a healthier nation. Since the war no nation had done so much, 2,670,000 new houses had been provided of a standard greatly improved in comparison with a quarter of a century ago.

International Congress on Life Assurance Medicine

The first International Congress on Life Assurance Medicine will be held in London from July 23 to July 26. The president is Sir Walter Langdon Brown and the honorary secretary Dr Otto May. The congress is concerned with the application of the results of modern medical research to the special problems of the selection of individuals for life assurance. One session will be devoted to the subject of health service and life assurance, and an exhibition in connection with it is being arranged by Dr Otto Neustatter of Berlin. July 23 a government reception will be held, when the minister of health will receive the guests.

The Employment of Married Physicians

The employment of married women is a vexed question. Some hold that married women should not by their competition be allowed to exclude from public appointments women who have to depend on their own exertions. On the other hand, those who believe in sexual equality hold that marriage should not be a bar to employment for women any more than for men.

This point is strongly insisted on by women's organizations. Some time ago the London County Council decided not to employ married women and to make marriage of its women employees a bar to further employment. The capture of the council by the labor party has produced a change. Various women's organizations sent deputations or made representations, all urging that married women be eligible for employment without restriction throughout the council's service. The general purposes committee of the council has made a report stating that the complexity of the question is such that any decisions must be in the nature of a compromise. The admission of married women must exclude from employment persons dependent on their own earnings in favor of an equal number for the most part not dependent. On the other hand, there are occupations in which marriage enhances the value of an officer. Considering the question from the point of view of the public service and not in the interest of any category, the committee has come to the conclusion that in two instances—the medical and teaching professions—material advantage to the public service would result if married women were eligible. "Not only do the duties of both doctor and teacher call for certain personal qualities which may be thought to be enriched by marriage, but the training of those entering these professions involves in many cases considerable expenditure of public money, the fruits of which are lost to the community if the career of every woman is terminated by marriage. We propose therefore, subject to certain limitations, that restrictions which at present debar married women in these professions from entering or remaining in the council's service shall be withdrawn." The limitations refer to practical difficulties. With regard to resident appointments, their holders must be available for duty when required at any hour of the day or night. Such demands are incompatible with the normal domestic and family responsibilities of a married woman. The committee therefore proposes that, excepting part-time consultants and specialists, all members of a hospital medical staff, including medical officers in the mental hospital service, and all teachers in residential appointments other than resident assistant nurses in special service institutions, should be excluded from the scope of the proposals. But in the case of the last-named exceptions difficulties will not arise if it is made clear to the staff concerned that marriage will involve their transfer to nonresident appointments. The council adopted the report by 76 to 37 votes.

Regulation of Automobile Lighting

New regulations designed to afford greater safety on the roads at night have been prepared by the minister of transport. They deal with dazzling headlights, variation in the height of lights and the practice of leaving stationary vehicles with head-lamps on. The new regulations provide that the beam from any electric lamp exceeding 6 watts in power, fitted to an automobile, shall either be permanently deflected or susceptible of deflection to such an extent that it is incapable of dazzling any person standing on the same horizontal plane as the vehicle at a greater distance than 25 feet from the lamp and whose eye level is not less than 3 feet 6 inches above that plane. The practice of leaving vehicles stationary with their head-lamps on also causes unnecessary danger and inconvenience on the road. The regulations prohibit the use of electric lamps exceeding 6 watts (a reasonable and normal power for side lamps) while the vehicle is stationary on a road. Another matter about which complaints have been made is the height at which front and rear lamps on some types of vehicles are carried. The new regulations provide that the front lights on a vehicle shall not be higher than 5 feet from the ground and that if the rear red light is at a height exceeding 3 feet 6 inches a red reflector and white patch similar to those used on pedal cycles shall be carried at or below that height.

Too Much Reliance on Laboratory Results

Several years ago, one of the heads of a large American clinic cited an instance of one of the younger clinicians asking for the roentgen examination of the teeth of a patient, without taking the trouble to examine the mouth and verify the fact that the patient had only false teeth. This example was quoted to demonstrate that one is apt to neglect physical examinations in favor of laboratory reports. An article by Charles Fiessinger along the same lines appeared in the June 8 issue of the *Journal des praticiens*. Faure, Sergent and Vires have recently directed attention to the fact that clinical diagnosis must be aided by laboratory results but that the latter ought not to replace the former. Some of the examples cited by Fiessinger may appear exaggerated, but there seems to be much truth in them. The presence of albumin in the urine is of much importance only when accompanied by other symptoms, such as hypertension or signs of renal insufficiency such as headache, or of cardiac decompensation such as dyspnea on exertion. Often the albuminuria may be due to disturbances of nutrition in the form of digestive disturbances. As to glycosuria, small quantities of sugar in the urine most commonly are of little significance. A restriction of carbohydrates will correct the condition in the majority of cases. In children, especially, small amounts of sugar in the urine do not justify a diagnosis of diabetes. The urea content of the blood is of value only if it remains high in successive analyses. Numerous persons are seen with a blood urea of from 60 to 100 mg per hundred cubic centimeters. If these are treated as nephritic, the urea will return to normal in a month and they will never later show a higher figure. Slight disturbance in liver action is often responsible for this transitory increase in blood urea, according to Noel Fiessinger. In such cases the treatment should be aimed at correction of the liver instead of at the renal disturbance. Acid fast bacilli which are thought to be tubercle bacilli, can be found on slides inadequately cleaned or even in ordinary tap water or the rubber tubing used in laboratories. The presence of tubercle bacilli in the sputum does not always signify an active pulmonary lesion. They are found in certain cases of bronchitis and pleurisy in which roentgenography fails to reveal any lesions. André Meyer has recently shown in a study of thirty cases of occult tuberculosis (pulmonary) that recovery occurs rapidly in the majority.

As to hypertension this is not a menace unless it rises to 280 or 300 mm of mercury. Hypertension is a serious condition only because of the underlying renal lesions that so frequently accompany it. Hypertension without such renal changes may exist for many years without resulting in the slightest accident. One often finds marked hypertension in very old persons. An increased diastolic pressure is of far more significance than an increased systolic rise. One must always bear in mind that the former condition may be transitory because of vascular spasm of nervous origin and is frequently observed in men active in business, lasting only a few weeks, and receding after an enforced absence from the strains of daily responsibilities. In women especially during the menopause, one is apt to find high blood pressure, which responds well to regulation of diet and rest. Diet, according to Fiessinger, is one of the best therapeutic aids especially in obese individuals and in cases of hypertension. Hypertension is a perfect phobia in many individuals. It is only a defensive reaction against interference with peripheral circulation, whether the latter is due to vascular spasm, to arteritis or to a renal lesion. The most important effect of high blood pressure is the extra work it places on the heart, hence, as soon as such a patient presents evidence of tachycardia digitalin in small doses should be

given for four days and continued if the tachycardia persists. If this is done, the "gallop rhythm" does not appear for a long time, perhaps never. Fiessinger cites some cases in which erroneous interpretation of roentgenograms has led to unnecessary operations. In one case a spasmodic contraction of the colon was interpreted as a neoplasm. The same is true of gastric radiography, so that in doubtful cases he puts the patient to bed for one to two weeks lessens the intake of food and gives atropine to exclude pyloric spasm and dextrose solution rectally to combat dehydration. If the defect persists, operation is indicated. Fiessinger in closing pleads for good clinical observation as a supplement to laboratory results. In the majority of cases a delay of two or three weeks will not jeopardize the patient's life. Laboratory studies may then be repeated and may give a different result. Most patients are in a hurry to have an exact diagnosis made but, when the advantages of further observation are explained few will object to waiting until possible sources of error in diagnosis are eliminated. Fiessinger's reputation as a clinician merits attention being given to his warning to correlate clinical and laboratory observations.

Vaccination Against Typhus with a Living Virus

At the April 2 meeting of the Academy of Medicine, the report of the Pasteur Institute of Morocco's experience with antityphus vaccination during the past two years was submitted by Blane and Gaud. They vaccinated 2180 natives with the virus of the murine type of typhus isolated from rats of Casablanca (Morocco). The virus was employed in a 1:500 or 1:1000 dilution to which 5 per cent by volume of sterilized oxbile was added. No vaccinal reaction was ever observed. Of the 2180 natives, there were 1149 men, 584 women and 447 children. The immunity enjoyed by one series of vaccinated, as well as the cessation of epidemics in two other localities has led Blane and Gaud to the belief that the use of a living virus mixed with bile will be successful in the future. It should be given as a prophylactic measure supplementary to delousing in every native community in which typhus is raging.

Evaluation of Previous Studies of Tubercle Bacillemia

An article from the Pasteur Institute of Paris has appeared on the frequency of finding tubercle bacilli in the blood of individuals suffering from a number of diseases usually considered as of nontuberculous origin. This article by the late Professor Calmette and Dr. A. Saez, one of his associates, is published in the fourth volume of the *Quarterly Bulletin* of the Committee on Hygiene of the League of Nations. The conclusions are the following: The Loewenstein medium is superior to all others for cultures of the human, bovine and avian types of tubercle bacilli. Only twelve positive results, i. e., 1.2 per cent, were obtained with this medium out of 936 blood examinations, a total of more than 6000 tubes.

These blood cultures were made from patients suffering from acute and chronic tuberculosis, rheumatism and dementia praecox. The cases of tuberculosis yielded only 1.58 per cent positive results and the appearance of the cultures showed that only a small number of tubercle bacilli were present, the majority being of the human type. Blood cultures from thirty-seven cases of acute or chronic rheumatism were all negative. The same was true of eighty-three cultures made from the blood and of sixty from the spinal fluid of patients suffering from dementia praecox. This marked difference from the relatively large percentage of positive results from blood cultures of the same diseases, as obtained by Loewenstein, cannot be ascribed to any errors of technic or sensibility of culture medium or to any lack of collaboration between the clinicians and the laboratory workers. The luxuriant aspect of the cultures obtained in Loewenstein's laboratory as well as the posi-

tive results obtained in stains of the blood used for inoculation from dementia praecox, erythema nodosum and polyarthritis have never been found either at the Pasteur Institute or at other laboratories, despite the efforts of a large number of well qualified investigators. Although the Loewenstein medium is superior to all others for the cultivation of tubercle bacilli, it is far less reliable for hemocultures of the tubercle bacillus than the guinea-pig, as brought out in a recent report (*Compt. rend. Soc. de biol.* 118:1159, 1935) by Saez, Costil and Sadet. Calmette and Saez believe that the Loewenstein technic affects the vitality of the tubercle bacilli.

First Lecture at Hôpital de la Pitié by Professor Clerc

Prof. A. Clerc, cardiologist, has begun a series of clinical lectures at the Hôpital de la Pitié, to which hospital he was transferred after many years of service at the Lariboisière Hospital.

BERLIN

(From Our Regular Correspondent)

June 17, 1935

Annual Session of the German Surgical Society

In April, the Deutsche Gesellschaft für Chirurgie held its annual session in Berlin. The attendance was 1,000. The main topic, 'Cancer' was opened by F. König of Würzburg, who discussed the question as to whether surgery can still regard carcinoma as a local disorder, his conclusions being for the negative. Observations extending over many years have shown that in addition to the cell degeneration that occurs in the primary focus, another, general factor facilitates the genesis of cancer. Evidence for this conception is the fact that frequently cancers that are histologically different from one another occur in the same person. The healing of cancer disease cannot be solved locally by a certain operation but is to a great extent subject to the influence of the general factors. The importance of the latter is shown by the fact that even with an evidently incomplete operation a recurrence is sometimes delayed for many years. Recurrences following sarcoma have often a different histologic character from the original tumor. On the other hand without an operation no cure is possible. Whether or not the effects of the operation will be enduring will depend on the general factors, for example, on the predisposition to cancer. This condition is not yet fully understood, but it can apparently be influenced. Probably postoperative irradiation produces a modification of predisposition and thus constitutes a valuable addition to the operation. Klein of Ludwigshaven believes he has isolated a cell-bound but labile agent with which, with a high degree of certainty, malignant tumors can be produced in animals. Substances that have been regarded in the past as productive of cancer, such as aniline and tar, are doubtless factors that break down the defense. Measurement of the defense forces in man is possible through a modification of the Freud method, with the use of which Klein states that he secured usable results in 90 per cent of the cases. This makes possible an early diagnosis of tumors, persons menaced might be detected and finally, the relative danger of a recurrence after an operation might be estimated. The substance that exerts a lytic action on the cancer cell is located in the reticulo-endothelial system, probably in the lymphocytes. Familial predisposition to cancer is based probably on a loss of defense forces of hereditary origin.

Hellner of Munster emphasized that the osteogenic sarcoma must be distinguished clinically, histologically and roentgenologically from the Ewing sarcoma, which constitutes 6 per cent of all bone sarcomas. Permanent cures as a result of roentgen irradiation have not been observed. Most, of Breslau, brought out that metastasis of mammary cancer to the supraclavicular glands occurs in three different ways, hence evacuation of these

glands as a fixed principle should be demanded. In scrutinizing the material of the Bier Clinic, Hintze of Berlin found cancer to be the second most common cause of intestinal occlusion. Only about half of such cases are amenable to a radical operation. Likewise lymphosarcomas may, by compression of the intestine or by causing intestinal invagination, give rise to intestinal occlusion. Schonbauer of Vienna emphasized that the indications for the irradiation of malignant tumors have narrow limits. For carcinoma of the tongue, the buccal mucosa and the tonsils, the best treatment is combined radium and roentgen irradiation following electrocoagulation of the tumor. Tumors of the larynx and the thyroid react well to rays, cancer of the penis to radium, likewise cancer of the portio vaginalis. Tumors of the extremities should, under all circumstances, be treated surgically. Ray treatment is not favorable in cancer of the esophagus and in tumors of the gastro-intestinal canal, with the exception of cancer of the anus. Schonbauer saw no good effects of irradiations in brain tumors.

During the discussion, Kirschner of Heidelberg took a critical stand toward the cancer reactions of Klein. In a series of 600 cases he obtained correct results in 82 per cent. Since the reaction is disturbed by fever, cachexia, roentgen irradiation and drugs, about 30 per cent of the patients have to be eliminated. Nevertheless, Kirschner regards the method in combination with other methods as valuable. According to other speakers, the method is not yet sufficiently developed for general use. Nevertheless, Hummel, of the Sauerbruch Clinic in Berlin, has reported satisfactory results.

The next main topic was "Sterilization." According to an inquiry instituted by K. H. Bauer of Breslau, the number of sterilizations carried out thus far (in the two sexes) was 45,000. A grave mental defect supplied the indications in more than 96 per cent of the cases. The percentage of hereditary bodily malformations, on the other hand, was small. In his collected statistics on some 6,000 cases only 0.19 per cent belonged to that category. Half of the sterilized men were from 20 to 35 years old. Even though the judge of the eugenics court decides in favor of sterilization and orders it carried out, the operator must take account of any contraindications, such as general disorders and already existing sterility. In man, the operation may be indicated up to age 70. Concerning the technic there is considerable uniformity, the operation is usually carried out under local anesthesia. The number of modifications, however, is manifold. Bauer recommends bilateral ligation and resection of two prepubic segments of the vas deferens. He rejects the scrotal operation. Complications of a psychic or reflexive nature were not observed after the operation. Hematoma, however, was noted in 1 per cent and infection in 0.7 per cent. In a series of 6,052 cases there were seven deaths (1.15 per thousand). The causes of death were pneumonia 2, cardiac weakness 1, myocarditis 1, epilepsy 1, erysipelas 1. In 85 per cent of the cases of the series the reason for the sterilization was unknown to the operator. The diagnosis should, however, be given to the physician even though the judge bears the responsibility for the indications.

Von Mikulicz-Radecki of Königsberg spoke on the "Sterilization of Women." The proportion of women already sterile is between 2 and 3 per cent. As a rule the abdominal operation should be applied to children and the vaginal operation to women who are already mothers. The supravaginal resection or total extirpation of the uterus is prohibited. The best procedure is excision of the intramural portion of the tube. In the whole series the average mortality was 0.4 per cent (circulatory weakness, pneumonia). The average duration of the hospital stay was sixteen days.

An animated discussion followed. Von Brandis reported his observations on 214 operations in the Freiburg clinic. Only in 15 per cent were motile spermatozoa demonstrable a week after the operation.

Bätzner of Berlin reported his experiences with a new anesthetic, divinyl ether, which is highly volatile and acts promptly, forty seconds after the anesthesia is started the operation may be begun, and the patient awakens almost immediately after the last drops are administered. The anesthesia can be readily controlled. On the other hand, a definite dosage (from 60 to 100 Gm) cannot be exceeded without danger, and the anesthesia cannot be extended beyond half an hour. Killian of Freiburg called attention to fatalities occurring in America.

The second day's session was devoted to thrombosis and embolism, the opening paper being presented by Stich of Göttingen. Postoperative embolism is never induced by one cause alone but always is due to several preconditions, which are associated with changes in the blood, the circulation or the vascular walls. The site of the thromboses that lead to an embolism is usually the femoral vein, at the point where it unites with the saphenous vein. The saphenous vein itself has little importance for the origin of an embolism. The deep veins of the calf and particularly those of the pelvis are more likely to be involved. The age of the patient plays a part, for often the necessary muscular play and secure closure of valves are lacking, which taken together may occasion a retardation of the circulation. If, in addition, there is a circulatory weakness, the preconditions for the development of a thrombus are soon present. The formation of a thrombus is facilitated by the fact that, as a person advances in age, the velocity of the circulation naturally decreases. Postoperatively one observes a changed composition of the blood. More particularly, from the fourth day on there is a shifting toward each other of the albumin and the globulin components. In young persons, however, all these changes do not suffice to produce a thrombosis, nor is a damage to the intima alone sufficient for the formation of a thrombus. It is primarily the inflammatory changes of the vascular walls that must be considered. Also electric storms and violent winds cause an increase of emboli, doubtless owing to their influence on the vegetative nervous system, the details of the mechanism are, however, not known. Statistics over long periods reveal that the proportion of fatal embolisms has remained about the same (from 0.2 to 0.3 per cent). The danger of embolism is almost nil in operations on the upper extremities, the neck and the thyroid. Exploratory laparotomy is more likely to produce embolism than are appendectomy and gastric resection (because one is dealing for the most part with inoperable carcinomas in elderly persons with existing acidosis). It is not the abdominal incision as such that constitutes the menace of embolism but the fundamental disorder. The highest percentages are found in prostatectomy and in operations on rectal carcinoma. It is important to prevent as far as possible the development of decomposition products by conservative destruction of the tissues during an operation. In Stich's comprehensive statistics 83 per cent of all embolisms were in patients more than 40 years old, two thirds in patients more than 50 years old, and 20 per cent in persons more than 70. Age plays a part, owing to dehydration of the tissues, also through increase of the blood pressure and impairment of the circulation. Obese persons, owing to the commonly existing circulatory disturbance, are particularly menaced. Preventive measures include reduction of operative injuries to a minimum, limiting as far as possible the thirst and hunger period, ample introduction of fluids before and after the operation getting up early or at least early exercise in bed in the form of movements of the legs or frequent changing of position, and frequent examination and strengthening of the circulation (strophanthin is more effective than digitalis, especially if combined with dextrose). The combating of postoperative acidosis is important. Therapy is almost powerless in dealing with embolism, operative treatment is but rarely indicated. If the attack is not fatal, active circulatory therapy is indicated, also sufficient quantities of narcotics to allay fear. Oxygen administration is absolutely necessary.

Payr of Leipzig pointed out that in inflammatory thromboses irradiation will cause swelling and pain quickly to recede, he recommends irradiation also in traumatic thromboses. Through the injection of from 20 to 40 cc of the patient's own blood when the patient was more than 20 years old, Specht of Frankfort-on-Oder reduced the cases of embolism to one in 5,000 patients, as compared with from 0.6 to 0.9 per cent in previous series of patients. The Gottingen physiologist Rein stressed emphatically that the acceleration of coagulation had nothing to do with thrombosis.

Rehn of Freiburg called attention in his paper on "The Menace of Operations" to the fact that all injuries resulting from operations or anesthesia are primarily circulatory injuries, which are not easily influenced by ordinary remedies. However, by means of a thyrotropic hormone an improvement may be secured, it brings about an increase in the total amount of blood in circulation and an augmentation of the basal metabolism. The danger lies in a simultaneous impoverishment of the liver glycogen, to combat which vitamin A should be administered.

The opening paper on the next main topic, 'Hemophilia,' was presented by Schloessmann of Bochum, who emphasized the hereditary factors. He stated that hemophilia is not observed in the colored races but reappears in half-breeds. Since the disorder is hereditary and is firmly rooted in all the body cells, a cure is impossible. However, a symptomatic improvement can sometimes be secured through the administration, for example, of vitamin C preparations.

The opening paper on the next main topic, 'Brain Surgery,' was presented by Sauerbruch. He opposed an exaggerated specialization in this field. The surgery of brain tumors, however, should be reserved to specialists. The chief dangers in brain operations lie in postoperative increased pressure and in postoperative hemorrhage. Sauerbruch operates with the patient in a sitting posture, in order to reduce as much as possible the flow of blood to the brain. By the inspiration of rarefied air a large quantity of blood is transferred to the lungs. Electrocoagulation signifies a distinct advance for brain surgery. The results as a whole, in spite of the great progress made by Cushing, are disheartening. It appears doubtful whether the surgeon will ever be able to dispense with the collaboration of the neurologist.

The opening paper on the final main topic, 'Surgery of the Prostate,' was presented by Voelcker of Halle. He prefers the perineal route. The mortality ranges between 7 and 15 per cent. Emboli are the most frequent cause of death. The functional tests are important. High blood pressure demands caution but is not a contraindication. Cancer of the prostate is difficult to diagnose, and a radical operation is not easily effected. Resection with the aid of the cystoscope constitutes a distinct advance in hypertrophy of the prostate.

Professor Lexer of Munich was chosen president of the society.

Marriages

VICTOR EUGENE FRAZIER, Hot Springs National Park, Ark., to Miss Annie Lee Daniel of Independence, Mo., June 18.

SIGURD B. GUNDERSEN, La Crosse, Wis., to Miss Eleanor Head of Madison, at Stamford, Conn., recently.

JOHN KEMP DAVIS, San Francisco, to Miss Edith Elizabeth Nash of Landrum, S. C., in Atlanta, June 16.

THOMAS W. MATTINGLY to Miss Frances Elizabeth Wannamaker, both of Washington, D. C., June 3.

JAMES ROBERT JACKSON, Belzoni, Miss., to Miss Anne Bagwell at Murfreesboro, Tenn., June 19.

DE WITT DOMINICK, Philadelphia, to Miss Elizabeth Lakin Pullman of Bridgeport, Conn., July 13.

WARREN MONROE GILBERT, Boulder, Colo., to Miss Mary Cuttino Harbin of Rome, Ga., May 21.

Deaths

George Milton Linthicum ☉ Baltimore, College of Physicians and Surgeons, Baltimore, 1893, member of the House of Delegates of the American Medical Association at a special session in February, 1935, since 1913 professor of diseases of the rectum and colon, University of Maryland School of Medicine, formerly professor of physiology and proctology, Baltimore Medical College, past president and vice president of the Medical and Surgical Faculty of Maryland, member and formerly vice president of the American Proctologic Society, fellow of the American College of Surgeons, served during the World War, consultant to the city health department, proctologist to the University of Maryland, Maryland General, Baltimore City and West Baltimore General hospitals, consultant to the Hospital for Consumptives, Towson, and Veterans' Administration, Perry Point, proctologist to the U. S. Marine Hospital for fourteen years, consultant in proctology and a member of the board of trustees of the E. C. Hazard Hospital, Long Branch, N. J., medical examiner for the Fidelity Life Insurance Company of America, aged 64, died, July 18, at his home in Roland Park, Maryland, of cerebral hemorrhage.

Louis Francis Jermain ☉ Milwaukee, Northwestern University Medical School, Chicago 1894, dean from 1913 to 1926, at which time he was elected dean emeritus, and clinical professor of medicine, Marquette University School of Medicine, past president of the State Medical Society of Wisconsin, Milwaukee County Medical Society and the Milwaukee Academy of Medicine, fellow of the American College of Physicians, in 1927 was decorated Knight of St. Gregory by the Pope, aged 67, on the staffs of the Milwaukee County Hospital and St. Joseph's Hospital, where he died, July 24, of diverticula of the colon, cirrhosis of the liver and coronary sclerosis.

Jesse Worthy Lea ☉ Jackson, La., Tulane University of Louisiana Medical Department, New Orleans, 1891, fellow of the American College of Physicians, formerly president of the East and West Feliciana Parish Medical Society, past president and counselor of the Sixth District Medical Society, served during the World War, for eight years on the staff of the East Louisiana State Hospital, and at one time on the board of administrators, aged 66, was found dead, July 9, of coronary occlusion.

Daniel Hamer Calder, Los Angeles, University of Vermont College of Medicine, Burlington 1895, member of the California Medical Association, formerly instructor and assistant professor in neurology and psychiatry, College of Physicians and Surgeons, medical department of the University of Southern California, for many years superintendent of the State Hospital, Provo, Utah, on the staff of the Los Angeles County Hospital, aged 62, died suddenly, July 19.

George D. Miller, Logansport, Ind., Central College of Physicians and Surgeons, Indianapolis, 1901, member of the Indiana State Medical Association, formerly secretary of the Cass County Medical Society, past president and secretary of the board of health of Logansport, at one time county coroner and state senator, on the staff of the Cass County Hospital, aged 61, died, July 19, of a skull fracture received in an automobile accident.

James Starr Hewson, Millburn, N. J., College of Physicians and Surgeons, Baltimore 1909, member of the Medical Society of New Jersey, police surgeon and member of the board of health of Millburn, served during the World War, aged 68, on the staffs of the Presbyterian Hospital and the Newark (N. J.) Beth Israel Hospital, where he died, July 8, of duodenal ulcer and pulmonary embolism.

Lawrence Hendee ☉ Buffalo, University of Buffalo School of Medicine, 1897, fellow of the American College of Surgeons, at one time assistant demonstrator of anatomy, Cornell University Medical College, Ithaca, N. Y., on the staffs of the Millard Fillmore Hospital, Buffalo, and the J. N. Adam Memorial Hospital, Perysburg, aged 58, died, June 27, of coronary occlusion and arteriosclerosis.

Edward Lewis Armbricht, Wheeling, W. Va., Jefferson Medical College of Philadelphia, 1892, member of the West Virginia State Medical Association, city councilman, for many years president and member of the board of education on the staffs of the Ohio Valley General Hospital and the Wheeling Hospital, aged 65, died, July 10, of coronary thrombosis.

Mariano Tolentino y Guerrero ☉ Manila, P. I., College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1910, formerly associate professor

of gynecology, University of the Philippines College of Medicine, on the staff of the Philippine General Hospital, aged 47, died recently, of cerebral hemorrhage

Robert Bronson Hartsfield ♂ Johnson City, N Y, Syracuse (N Y) University College of Medicine, 1928, formerly assistant professor of pathology at his alma mater member of the Medical Society of the State of New York; aged 36, was drowned, July 8, when his automobile plunged into a canal

Orville Lee Baldwin ♂ Columbus, Ohio Rush Medical College, Chicago, 1922, member of the American Academy of Pediatrics, on the staffs of the Grant, White Cross, St Ann's and Children's hospitals, aged 41, died June 9 of coronary thrombosis, while attending a meeting in New York

Elwood Palmer Spencer, Cooperstown, Pa University of Pennsylvania Department of Medicine Philadelphia, 1903 member of the Medical Society of the State of Pennsylvania, aged 68, on the staff of the Franklin (Pa) Hospital where he died, July 2, following an operation for appendicitis

Harry Wilson Stout ♂ Wenonah, N J, University of Pennsylvania School of Medicine, Philadelphia, 1917 past president of the Gloucester County Medical Society, aged 44 on the staff of the Underwood Hospital Woodbury, where he died, June 29, of acute dilatation of the heart

Robert Elwood Heimbach ♂ Castle Point, N Y Cornell University Medical College, New York 1923, member of the Medical Society of the State of Pennsylvania, served during the World War, aged 40, died, May 25, in the Veterans Administration Facility of pulmonary tuberculosis

Manyard H Davis ♂ Mays Lick Ky University of Louisville Medical Department, 1881 in 1929 member of the House of Delegates of the American Medical Association, aged 75, died, June 14, in the Christ Hospital, Cincinnati, of hypertrophy of the prostate and pulmonary embolism

Joseph Wellington Schoffstall ♂ Sunbury, Pa Jefferson Medical College of Philadelphia, 1902, served during the World War, on the staff of the Mary M Packer Hospital, aged 55, died, June 23, in the George F Geisinger Memorial Hospital, Danville, of cerebral thrombosis

John Norfolk Morris, Sykesville, Md, University of Maryland School of Medicine, Baltimore, 1893, member of the Medical and Surgical Faculty of Maryland on the staff of the Springfield State Hospital, aged 62, died, June 22, of peptic ulcer

John Edgar Getman ♂ New York, Columbia University College of Physicians and Surgeons New York 1899 served during the World War on the staffs of St Luke's and Post-Graduate hospitals, aged 58, died, June 12, of heart disease, at Brewster, N Y

Luther Herbert Thomas, Branchville, S C Medical College of the State of South Carolina Charleston, 1910 formerly mayor, member of the South Carolina Medical Association, member of the board of health, aged 50, died, June 20, of heart disease

William P Love, Youngstown Ohio, Western Reserve University Medical Department, Cleveland 1896, member of the Ohio State Medical Association, veteran of the Spanish-American and World wars aged 64, died, July 11, of cerebral hemorrhage

Frederick Van Vliet, New York, College of Physicians and Surgeons, Medical Department of Columbia College, New York, 1895, aged 63 died, July 8 in the Kings County Hospital Brooklyn of meningococcal meningitis and cerebral thrombosis

Christus A Derebey, Chicago, Northwestern University Medical School, Chicago 1897 member of the Illinois State Medical Society, aged 78, on the staff of the Belmont Hospital where he died, June 25, of chronic endocarditis and arteriosclerosis

Emil Joseph Susslin ♂ Bridgeport, Conn University of Vermont College of Medicine Burlington, 1921, aged 37, on the staffs of the Englewood Hospital and the Bridgeport Hospital where he died, July 9, of subacute bacterial endocarditis

Park Alfonso Findley ♂ Des Moines Iowa, Drake University Medical Department Des Moines 1895, formerly sheriff of Polk County and chief of the Iowa State Bureau of Criminal Investigation, aged 60, died suddenly, June 13 of heart disease

Edwin Harwood Smith ♂ Bemidji Minn University of Minnesota College of Homeopathic Medicine and Surgery, Minneapolis 1900 city health officer on the staff of the Lutheran Hospital aged 59, died July 7, of lobar pneumonia

George Guy Snyder, Harrisburg, Pa, Medico Chirurgical College of Philadelphia, 1899, member of the Medical Society of the State of Pennsylvania, since 1919 county prison physician aged 59, died, July 13, of hypertension and uremia

David Howard Cooper, Pittsburgh, University of Pittsburgh School of Medicine, 1923 on the staffs of the Homestead (Pa) Hospital and the Montefiore Hospital, aged 37, died suddenly, June 12, of coronary occlusion

Samuel Omer Barwick, Elkhart, Ind, Eclectic Medical Institute, Cincinnati 1894, member of the Indiana State Medical Association, aged 72, on the staff of the Elkhart General Hospital, where he died, July 7, of pneumonia

Edwin Remick, Tamworth, N H, University of Vermont College of Medicine, Burlington, 1894, member of the New Hampshire Medical Society aged 69, died, June 2, of chronic myocarditis and acute pulmonary edema

Myra Brown-Tynan, Portland, Ore., Willamette University Medical Department, Portland, 1889, for seventeen years connected with the city health department, aged 67, died, June 20, of cerebral hemorrhage

Peter T Barnum Shaffer, Elizabeth, Pa, Western Reserve University Medical Department, Cleveland 1877, member of the Medical Society of the State of Pennsylvania, aged 85, died, June 25, of carcinoma of the stomach

James Thomas Flannigan, Sinclairville, N Y, University of Buffalo School of Medicine, 1928 aged 32, on the staff of the Jamestown (N Y) General Hospital, where he died, May 25, of encephalomyelitis

Charles Wilber Seever, Sheldon, Ill, Chicago College of Medicine and Surgery, 1909, served during the World War, aged 54, died, July 4, in the Garfield Park Hospital, Chicago, of cirrhosis of the liver

Benjamin L Clifton, Millen, Ga, Southern Medical College, Atlanta, 1885, member of the Medical Association of Georgia, aged 77, died, June 7, of cerebral hemorrhage and acute nephritis

Albert Lewis Martin, Wyandotte, Mich, State University of Iowa College of Homeopathic Medicine Iowa City, 1887, aged 68, died, July 20, at his home in Trenton, of cerebral hemorrhage

William Altman ♂ Cleveland, Ohio State University College of Homeopathic Medicine Columbus 1916, aged 47 died, July 16, of chronic myocarditis, heart disease and pulmonary edema

Duffield Roy Kruger, Manila, P I, Kansas City (Mo) College of Medicine and Surgery 1916, aged 41, died suddenly, April 6, in St. Paul's Hospital, of pulmonary embolism

Edward Bates Clements, Macon Mo, Howard University College of Medicine, Washington, D C, 1881, aged 74, died, June 19, of injuries received in an automobile accident

Alton R Danforth, Norcross Ga, Southern Medical College, Atlanta 1890, aged 76, died, June 5 in a hospital at Atlanta, of chronic nephritis and cirrhosis of the liver

Earle Rice Davis, Renovo, Pa, Hahnemann Medical College and Hospital of Philadelphia, 1917, served during the World War, aged 40, died June 15, of heart disease

John Thomas Edwards, Glencoe, Ala, University of Tennessee Medical Department, Nashville 1890, aged 78, died, May 26, of hypostatic pneumonia and arteriosclerosis

Edward James McConaghy, Audubon, N J, Jefferson Medical College of Philadelphia, 1911, aged 52 died, June 18, in the Lakeland Sanatorium, Glenloch, of pneumonia

John Daniel Grant ♂ Allock, Ky, University of Louisville Medical Department, 1917, past president of the Perry County Medical Society, aged 45 died, June 2

Charlie Bib Townes ♂ Tahoka Texas Vanderbilt University School of Medicine, Nashville, Tenn, 1908, aged 58, was killed, July 10 in an automobile accident

William Hastings Dial, Laurens, S C, University of Maryland School of Medicine, Baltimore, 1884, formerly mayor, aged 75, died, June 1

Archie Royal Fleming, Suffolk, Va, Howard University College of Medicine, Washington, D C, 1919, aged 43, died, April 10, of angina pectoris

Albert Emmons Connell, Cleveland, Western Reserve University Medical Department, Cleveland, 1904, aged 62, died, June 12, of myocarditis

Robert Benjamin Killian, Lincolnton N C Louisville (Ky) Medical College, 1885, aged 79, died, June 26, of carcinoma of the colon

Bureau of Investigation

MISBRANDED "PATENT MEDICINES"

Abstracts of Notices of Judgment Issued by the Food and Drug Administration of the United States
Department of Agriculture

[EDITORIAL NOTE The abstracts that follow are given in the briefest possible form (1) the name of the product, (2) the name of the manufacturer, shipper or consigner, (3) the composition, (4) the type of nostrum, (5) the reason for the charge of misbranding and (6) the date of issuance of the Notice of Judgment—which may be considerably later than the date of the seizure of the product]

Captain Bryant's Grand American Remedy—F W Bryant Scranton Pa Composition Essentially volatile oils including those of pepper mint and red peppermint with alcohol water and red coloring For stomach disorders diarrhea toothache dyspepsia etc. Fraudulent therapeutic claims—[N J 21983 September 1934]

Curry's Headache Powders—Curry Arrington Co Rome Ga Composition Essentially 24 grains of acetanilid 0.94 grain of caffeine and 15 grains of baking soda in each powder Misbranded because amount of acetanilid per powder was not declared on the label as required by law misbranded further because of fraudulent therapeutic claims—[N J 21984 September 1934]

Breeden's Blood Medicine—Breeden Drug Co Inc Memphis Com position Essentially potassium iodide extracts of plant drugs and alcohol (14.2 per cent by volume) Fraudulent therapeutic claims—[N J 21993 September 1934]

Copinol—Copinol Co Los Angeles Composition Essentially mineral oil with a trace of an alkalioid such as berberine and perfume For catarrh hay fever sinus trouble etc. Fraudulent therapeutic claims—[N J 21994 September 1934]

Hutchison's Antiseptic Healing Oil—Hutchison Medicine Co Tex arkana Texas Composition Essentially volatile oil such as sassafras and turpentine with carbolic acid a vegetable oil such as linseed and mineral oil (about 75 per cent) For eczema itch piles boils etc. Fraudulent therapeutic claims—[N J 21995 September 1934]

Kulnow's Anti Asthma Powder—Hutchison Medicine Co Tex arkana Texas Composition Essentially saltpeter and plant material such as stramonium or belladonna Fraudulent therapeutic claims—[N J 21995 September 1934]

Nash's Salve—Hutchison Medicine Co Texarkana Texas Com position Essentially volatile oils including menthol, camphor eucalyptus sassafras and turpentine in a mixture of glycerin and petrolatum For coughs catarrh asthma piles boils tonsillitis etc. Fraudulent therapeutic claims—[N J 21995 September 1934]

Bamaoca Oil—Bamaoca Co Boston Composition Essentially small amounts of volatile oils including wintergreen spearmint and rosin in mineral oil Cure-all Fraudulent therapeutic claims—[N J 21996 September 1934]

Bamaoca Salve—Bamaoca Co, Boston Composition Essentially a small amount of volatile oil such as spearmint in a mixture of petrolatum and rosin For boils carbuncles, tonsillitis pneumonia appendicitis peritonitis etc. Fraudulent therapeutic claims—[N J 21996 September 1934]

Gastralint—Bamaoca Co Boston Composition Essentially starch sugar and a small amount of a fatty acid such as stearic acid in tablet form For dyspepsia, gastritis, heartburn nervous prostration etc. Fraudulent therapeutic claims—[N J 21996 September 1934]

Nanzetta's New Prescription—Composition Essentially plant drug extracts including cascara sagrada licorice and sarsaparilla with alcohol (81 per cent by volume) and water For rheumatism impure blood liver and stomach disorders etc. Misbranded because quantity or proportion of alcohol not declared on label and because of fraudulent therapeutic claims—[N J 21998 September 1934]

Zepyril—Stearns Hollinshead Co Inc Portland Ore. Composition Small amounts of zinc chloride common salt, glycerin saccharine alcohol (25 per cent by volume) and water colored and flavored For skin diseases tonsillitis influenza catarrh etc. Not antiseptic or germicidal as claimed. Fraudulent therapeutic claims—[N J 22002 September 1934]

Beatsel Earache Outfit—G & W Laboratories Inc. Jersey City N J Composition Essentially ether camphor eucalyptol and alcohol Fraudulent therapeutic claims—[N J 22003 September 1934]

Oyster X Tonic—Oyster X Co Cleveland Composition Tablets containing material derived from nux vomica, calcium iron and aluminum compounds traces of copper iodine manganese and phosphorus compounds proteins and starch. For blood building etc. Misbranded because the ingredients named were present in insignificant amounts and because the statement government inspected was false. Fraudulent therapeutic claims—[N J 22004 September, 1934]

Mother Gray's Sweet Powders for Children—A S Olmsted Co, Le Roy N Y Composition Essentially sulphur baking soda, licorice, starch and sugar For stomach liver and digestive disorders Fraudulent therapeutic claims—[N J 22005 September 1934]

Force—Union Pharmacal Co Kansas City Mo. Composition Essentially plant drug extracts including a laxative with phenolphthalein, phosphoric acid alcohol sugar and water For debility anemia, physical and mental exhaustion etc. Fraudulent therapeutic claims—[N J 22009 September 1934]

Her Villa—Anglo American Pharmaceutical Corporation and Huxley Laboratory Inc New York Composition Essentially the glycerophosphates and formates of calcium, iron manganese, sodium and potassium, with strychnine glycerin sugar and water For weak nerves anemia debility etc. Fraudulent therapeutic claims—[N J 22013 September 1934]

X Z Mex—Dr Jayess Pharmacal Products Allston Station Boston. Composition Essentially zinc oxide (53 per cent) salicylic acid (11 per cent), sodium salicylate (13 per cent) mercurous chloride (2.2 per cent) volatile oil such as cade oil (1 per cent) and water (47 per cent) incorporated in petrolatum For eczema psoriasis ulcers dandruff etc. Fraudulent therapeutic claims—[N J 22012 September 1934]

The \$20 000 A Dose Discovery—C Neil Simpson Houston Texas. Composition Essentially a mixture of zinc sulphate and powdered digitalis leaves For blood disorders syphilis and other venereal diseases, cancer ulcerated stomach piles boils pellagra etc. Fraudulent therapeutic claims—[N J 22014 September 1934]

Rainey's Vitality Tablets—Dr Rainey Drug Co Chicago Composition Calcium carbonate metallic iron iron carbonate and plant drug extracts including cinchona and nux vomica For anemia, indigestion, neurasthenia etc. Fraudulent therapeutic claims—[N J 22180 September 1934]

Rainey's Laxatives—Dr Rainey Drug Co Chicago Composition Uncoated tablets containing calcium carbonate plant drug extracts including nux vomica and a laxative and a small amount of an iron compound. For liver disorders stomach catarrh, etc. Fraudulent therapeutic claims—[N J 22180 September 1934]

Hiseen—Hiseen Corporation Chicago Composition Essentially phenobarbital atropine and a small amount of plant material For asthma hay fever and bronchitis Misbranded because labeled "Non-habit forming" also because of fraudulent therapeutic claims—[N J 22016 September 1934] This nostrum was the subject of a detailed article that appeared in this department of THE JOURNAL, Oct. 14 1933

Colonald—Norwood Pharmaceutical Co Inc. and Clyde F Lloyd, Chicago Composition Essentially milk sugar casein dextrin and smaller amounts of starch phenolphthalein calcium phosphate a potassium compound and carbonates For stomach and bowel troubles, auto-intoxication etc. Misbranded because called harmless natural laxative food which it was not also because of fraudulent therapeutic claims—[N J 22019 September 1934]

Anti Cholelith—Leon Chemical Co Springfield Mo Composition Essentially plant drug extracts including hydrastis and a small amount of acetic acid with glycerin and water For gallstones kidney stones, auto-intoxication indigestion constipation etc. Fraudulent therapeutic claims—[N J 22191 September 1934]

Silver Salve Gall Remedy—Diehl Chemical Co Omaha Composition Zinc oxide (9 per cent) and a small amount of benzaldehyde in a mixture of petrolatum and fat colored blue For old sores wounds ringworm protruding piles varicose veins eczema etc. Fraudulent therapeutic claims—[N J 22193 September 1934]

Ensign Remedies—Ensign Co Battle Creek Mich. Composition Remedy No 42 99.6 per cent of sugar Remedy No 7 99.2 per cent of sugar no therapeutic agents found. Fraudulent therapeutic claims for Remedy No 42 as cure for primary syphilis etc. and for Remedy No 7 as a cure for la grippe influenza, etc.—[N J 22196 September 1934]

Cascara Cold Breakers—National Pharmacal Co Detroit Composition Acetanilid (17 grains) small amounts of plant drug extracts including a laxative drug ammonium chloride camphor red pepper and sodium salicylate and a trace of a drug containing a mydriatic alkalioid. Adulterated because below professed standard of purity and strength misbranded because quantity and proportion of acetanilid not declared on label and also because of fraudulent therapeutic claims—[N J 22195 September 1934]

Petro Ido—White Specific Toilet Co, Nashville Tenn Composition 0.05 per cent of iodine dissolved in mineral oil For stomach ulcer appendicitis typhoid stomach cancer high blood pressure heart trouble, etc. Fraudulent therapeutic claims—[N J 22198 September 1934]

Santay Swiss Anti Diabetic Tea—Modern Health Products Inc., Milwaukee Composition Plant drugs including peppermint leaves and stems malva flowers senna pods and dog grass. Fraudulent therapeutic claims—[N J 22199 September 1934]

Nutro Links—Modern Health Products, Inc Milwaukee Composition Formulas No 5 and No 6 and No 6 Tablets Powdered plant material common salt and Glauber's salt. For rheumatic conditions. Fraudulent therapeutic claims—[N J 22199 September 1934]

Black's Browe Powder—Dr W E. Black Co Dallas Texas. Composition Essentially baking soda magnesium carbonate and an iron compound For acidosis gastritis ulceration kidney disorders etc. Fraudulent therapeutic claims—[N J 22302 November 1934]

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted on request.

EARLY DIAGNOSIS OF TUBERCULOSIS

To the Editor—*I thoroughly enjoy reading Queries and Minor Notes of particular interest to me were the articles on tuberculin testing appearing in the issues of May 26 and Sept 22 1934. Please allow me to discuss briefly one phase in the last part of your answer to Dr. Billard (Sept 22 1934 p 935).*

In the finding of the first infection focus of tuberculosis which practically always results in a positive tuberculin reaction the x-ray film is of little avail. By it 75 per cent or more of the lesions are missed, as demonstrated by Miller (*Am. J. Roentgenol.* 20:191 [Aug.] 1931) and others who have carefully studied x-ray films made ante mortem and compared the observations with what has been found post mortem.

I think that Dr. Miller's observations in the recognition of thoracic calcifications are accurate. However in your answer an inference might be drawn that 75 per cent of serious lesions were missed by roentgen examination. This is probably not the way you meant it. However, I will discuss briefly the question of roentgen examination and tuberculin testing from a practical point of view. Positive reactors denote live tubercle bacilli in the body; the x-ray film shows whether or not there are serious lesions in the lungs. It is well known that with a good roentgenogram, gross or serious lesions, which soon prove fatal to the patient, are seldom missed. Now are small primary lesions and calcification and enlarged tracheobronchial lymph nodes serious? All admit that the latter types of patients and all positive reactors should have repeated roentgen examinations in order to pick up serious lesions if they develop.

During the past six years in the Los Angeles County Health Department, out of some 15,000 children who were positive reactors and who were negative for pulmonary tuberculosis by roentgen examination only six in the calcified and enlarged lymph node group were found to have developed pulmonary tuberculosis (reinfection). Two of these active cases were in known contacts. The majority of positive reactors have been rechecked several times by x-rays and are consistently negative. All active cases are of course, isolated from the rest of the family when ever possible. However this is many times impossible as a high percentage of our patients are Mexicans whose home conditions are undesirable.

This is our plan which I think is practical for it is working.

All positive reactors are roentgenographed and the following essential points are taken into consideration:

1. Has the patient pulmonary tuberculosis? If so will he infect others?
2. Is the patient suitable for sanatorium care?
3. Is the patient suitable for collapse therapy?
4. Has the patient demonstrable enlarged lymph nodes or calcified lesions? If so are they considered serious?

(The following discussion is confined principally to point 4.)

We do not consider calcification and enlarged lymph nodes serious at the moment. These patients will not infect others and will not die from these types of lesions.

Is this type of patient suitable for preventorium or sanatorium care? Usually not. If all these patients were sent to sanatoriums there would not be sufficient accommodations. Furthermore beds would be filled with clinically well patients. If the home conditions are good even the patients who have small primary uncalcified lesions are seldom sent to sanatoriums, as the lesions usually disappear within six months.

The method we use when we find a small lesion in the lung (in order to rule out bronchopneumonia) is to recheck roentgenographically within a month. If the lesion persists we consider it tuberculous.

It is not my wish to enter into a controversy regarding endogenous and exogenous tuberculous infection as I feel that this is a two-sided question, and the correct answer may not be forthcoming for several years. However, Professor Blacklock has shown by many autopsies that in no instance has there been a retrograde spread from the tracheobronchial lymph nodes back into the lung substance, and he concluded that the lymphogenous origin of the primary infection is unlikely (*Tuberculous Disease in Children: Its Pathology and Bacteriology*, Special Report Series No. 172, Medical Research Council Glasgow, Scotland).

I think that roentgen examination is of major importance in all suspected cases of tuberculosis as serious lesions can be immediately ruled out. After all this is of primary concern. We tuberculosis workers are inclined to be so scientific that we fog the issue. The novice doesn't know how to interpret our observations.

MERRI LEE PINDELL, M.D., Los Angeles.

Roentgenologist for Los Angeles County Health Department

ANSWER.—The statement that 75 per cent or more of lesions of the first infection type of tuberculosis are missed by roentgen examination was intended to emphasize the fact that the x-ray film is a gross method of locating lesions of this type but that the tuberculin test is a delicate method of finding such cases. Many workers have been of the opinion that if the roentgen examination does not reveal a lesion none exists and have expressed the belief that such persons are only

infected and do not have disease. This statement by no means discredits the value of the x-ray film but only points out the helplessness that still exists in the attempt to locate the site of the lesion in large numbers of persons who have tuberculosis.

The question has been raised as to whether the first infection type of tuberculosis either in the inflammatory stage and sufficiently large as even to be mistaken for pneumonia by roentgen examination alone, or in the calcified stage, may ever be considered serious of itself. Apparently nearly all the serious lesions are produced by reinfections. The belief that reinfections are frequently from endogenous sources is gaining ground as indicated by such workers as Miller (*Ann. Int. Med.* 8:243 [Sept.] 1934). Therefore, one must look on every first infection type of lesion, whether or not it is demonstrated roentgenographically, as having serious potentialities through providing tubercle bacilli, which are transmitted elsewhere, where they often set up serious reinfection types of lesions. From such studies as those made by Chadwick (*School Physicians' Bull.*, October 1934), Myers and Harrington (*THE JOURNAL*, Nov. 17, 1934, p. 1530) and Stewart (*THE JOURNAL*, April 8, 1933, p. 1077) it appears clear that children with the first infection type of tuberculosis, which has caused them no illness, are many times more likely to develop serious lesions in later life than children who have not developed the first infection type of disease. Therefore, in roentgen examinations the chief concern should be not with finding the first infection type of lesion, since the positive tuberculin reaction has already shown that it exists, but rather with finding the reinfection type, to which the term "serious" is always justifiably applied, no matter how small the lesion may appear. This fact should justify the making of x-ray films periodically of every positive reactor.

The chronic reinfection type of pulmonary tuberculosis is not frequently seen until adolescence approaches. Therefore it has been suggested that periodic x-ray film work of positive reactors begin at about that age except among children with other manifestations of disease or when funds are not a problem.

The fact that six cases of the reinfection type of tuberculosis have already been found among 15,000 children under observation only six years is of considerable significance, since tuberculosis is a communicable disease. If the group of children at Los Angeles is similar to those observed elsewhere, this number will be markedly increased if they are kept under observation until even the age of 25 years is reached. It has been said that it seems remarkable that probably from thirty to forty million persons in the United States would react positively to the tuberculin test and that the number with clinical tuberculosis is relatively small. One must not neglect the fact that nearly all of the remaining eighty to ninety million persons in this country who probably would react negatively to the tuberculin test are free from clinical tuberculosis, that is, the thirty to forty million with positive reactions provide practically all the tuberculosis load of this country.

The plan of procedure described is excellent. Under point 1 the correspondent doubtless has in mind the reinfection type of pulmonary tuberculosis. The question as to whether such patients are suitable for sanatorium care or collapse therapy must always be determined for the individual case, depending on the extent of disease, whether it is unilateral or bilateral, whether it has broken down so that the patient is disseminating tubercle bacilli, whether the home conditions are such that one is justified in beginning collapse therapy, and whether the patient's temperament is one that will require much discipline. All these and many other points are doubtless taken into consideration in determining which form of treatment shall be employed, each is good in its place.

Under point 4 there is no doubt that those who have observed large numbers of children with the first infection type of disease over many years will agree that calcification and enlarged lymph nodes are not serious at the time. They will also agree that preventorium and sanatorium care usually are not indicated. The method of rechecking when a small lesion first makes its appearance in the lung is ideal, for certainly no one by an x-ray film or physical examination can differentiate between small lesions of pulmonary tuberculosis and bronchopneumonia.

As Professor Blacklock's studies were based entirely on post-mortem examinations, it is obvious that he had the opportunity of making only the final examination. While it is true that this is the most accurate method of making an examination, it is also true that serial examinations of lesions by x-ray film and other methods over long periods of years is the only method by which one can trace the actual evolution of tuberculosis.

CONTAGIOUS ABORTION IN CATTLE

To the Editor—Recently I have been asked a number of questions about contagious abortion in cattle that are too much for me. 1 Is it the same disease as Malta or relapsing fever? 2 Is it transmitted through cow's milk? 3 Is cooking in ordinary ways sufficient sterilization of the meat of an aborting cow? 4 Is there any danger in feeding milk of such cows to chickens or hogs? 5 Is the blood test as done by federal veterinary surgeons a reliable test? 6 Would a positive test on a cow that has never aborted and is symptom free be enough evidence to justify destruction of the cow? 7 Is a cow that is a reactor but has never aborted and is symptom free a menace to other cattle in the same herd? Will you please cite references to authorities as this is quite an important question in the community just now.

E R HUCKLEBERRY, M D Garibaldi, Ore

ANSWER—1 Malta fever, now more commonly called undulant fever or brucellosis and contagious abortion in cattle are caused by the same etiologic agent, *Brucella*. Relapsing fever is quite a different disease, caused by several varieties of spirochetes belonging to the genus *Spirillum*.

2 Brucellosis in human beings is commonly transmitted through raw cow's milk or unpasteurized dairy products.

3 Yes

4 There is danger in feeding the milk of cows with *Brucella* infection to hogs. Emmel and Huddleson have isolated *Brucella* from the domestic fowl in a naturally infected flock and have produced the disease in several breeds of fowl, usually with fatal termination, after feeding the fowl on mash containing *Brucella*.

5 Yes

6 Such a cow should be isolated from noninfected animals or destroyed.

7 Yes

ASTHMA AND INFECTION AFTER EXPOSURE TO SULPHUR DIOXIDE

To the Editor—I have seen several cases of asthma and chronic pulmonary infections that developed apparently after exposure to irritating sulphur dioxide gas. I have looked for literature on this phase of the relationship of sulphur dioxide exposure toward the causation of acute and chronic episodes of pulmonary disease but find the literature wanting.

NAT SPITZER, M D New York

ANSWER—The total number of cases of proved damage from exposure to sulphur dioxide gas is not sufficiently high to lead to statistical arrangements. Many of these cases have followed exposure to sulphur dioxide gas in the manufacture of electrical refrigerators, other cases have resulted from leaks in refrigerator equipment after installation in homes, hotels and elsewhere, still other cases have appeared in connection with claims against the owners of burning gob piles connected with coal mines. In the following publications may be found extensive comment relative to the action of sulphur dioxide on the respiratory tract.

- Encyclopedia of Pathology, Hygiene and Social Welfare volume 2 No 31. International Labor Office Geneva 1930.
Journal of Industrial Hygiene 14: 159 (May) 1932.
Bulletin 582 U S Bureau of Labor Statistics page 45.
Henderson and Haggard. Noxious Gases and the Principles of Respiration Influencing Their Action. New York Chemical Catalog Company 1927.

From the first mentioned a brief excerpt is quoted.

"With those not accustomed to it sulphur dioxide in quite weak concentration produces an acid taste in the mouth an increased flow of saliva and irritation of the nasal ocular and respiratory mucous membranes. Its action is less irritating to

the conjunctival than to the respiratory mucous membrane, in which area sneezing and attacks of coughing occur which are often spasmodic. If the action is too severe or too prolonged then catarrhal inflammation, either bronchial or pulmonary, occur with viscid, often blood stained expectoration. In some cases congestion and pulmonary asthma have been noticed. Serious cases caused by this gas are rarely fatal."

From the second cited publication a similar extract is presented.

"Exposure to sulphur dioxide under the conditions observed (100 subjects, forty-seven of whom had had from four to twelve years of exposure in the plant of one of the large manufacturers of electrical refrigerators) produces two distinct sets of effects (1) irritation of the upper respiratory tract, which is at first acute in character, and subsequently subacute or chronic, and (2) systemic symptoms of a mild type such as are associated with any type of increased acid absorption or production in the tissues."

In the fourth citation the following may be found not all of which is exclusively with reference to sulphur dioxide.

"Although the action of sulphur dioxide is mainly in the upper respiratory tract, severe exposure causes inflammation of the bronchi and lungs. The outstanding feature of inflammation in the lungs resulting from the action of irritant gases is pulmonary edema. The condition reaches its height in from twelve to twenty-four hours after the exposure. If death does not occur it tends to regress within forty-eight hours."

"The edema induced by irritant gases differs from the edema of nonirritant origin in that the latter is usually particularly marked in the pendent portion of the lungs, while the edema arising from irritation is not greatly affected by gravity or the posture of the subject. Not all parts of the lungs however, are equally involved in the inflammatory changes arising from the action of irritant gases. The irritant action upon the smaller bronchial tubes may cause some of them to contract so that the portions of the lungs to which they lead escape the action of the gas. Owing to this bronchoconstriction as well as to the plugging of the bronchi with sloughed mucosa and fibrin, areas of atelectasis and emphysema may occur in the edematous lung."

While some persons become inured to the action of fairly high concentrations of this gas and apparently are no longer irritated through prolonged day by day exposure, other persons apparently develop no protective mechanisms and readily present on trivial exposure, such as from 15 or 20 parts of the gas to a million parts of air, manifestations of irritation of the respiratory tract including on occasion typical asthmatic characteristics.

NONPROTEIN NITROGEN RETENTION

To the Editor—In an arthritic patient with a history of suppurative otitis media and acute mastoiditis fifteen years ago what significance would be given to a nonprotein nitrogen retention of 60 mg with no evidence in the urine of albumin or kidney degeneration? At present there is no evidence of ear disease except deafness and roentgen examination of the mastoid region shows some destruction of the mastoid cells. I might add that the patient has had several acute exacerbations of chronic polyarticular arthritis during the past fifteen years confining him to bed for a period of three months on two occasions.

J N CROSS M D, Alexandria Ohio.

ANSWER—The normal nonprotein nitrogen is usually between 25 and 35 mg per hundred cubic centimeters of blood. The figures run parallel to the urea estimation, so that little information is gained that cannot be more accurately and easily obtained by urea nitrogen estimation. With mild impairment of renal function the urea nitrogen often reaches from 16 to 30 mg and the nonprotein nitrogen from 30 to 60 mg. There are many causes of an elevated urea or nonprotein nitrogen.

- 1 Bilateral diffuse kidney disease (acute subacute chronic or hypertensive)
- 2 Congenital polycystic kidneys
- 3 Pyelonephritis or pyonephrosis
- 4 Poisoning with heavy metals
- 5 Passive congestion of the kidneys
- 6 Dehydration probably compensatory to maintain the osmotic pressure of the plasma at a normal level after excessive loss of salts from vomiting, diarrheas and so on
- 7 Obstruction in the urinary tract, especially when bilateral

Many of the foregoing causes of increase in the nonprotein nitrogen can be determined by the history, physical examination, and careful examination of the urine.

In the case cited, the presence of focal infection in the middle ear and mastoid, and several attacks of rheumatic fever suggest the possibility of a nephritis. In most cases repeated urine examinations will reveal some albumin, casts or blood cells. A nonprotein nitrogen of 60 mg on repeated examination speaks for some form of renal damage listed.

ALKALINITY OF URINE

To the Editor—I have a patient whose urine is persistently alkaline. When the urine is alkaline there is frequent and painful urination. The only other abnormality found in the urine is the presence of considerable amounts of mucus. All the usual drugs for acidification of the urine have been tried with only temporary and partial amelioration of the symptoms. Daily irrigation of the bladder with boric acid solution affords the patient the greatest degree of comfort of any of the measures tried. Irrigations of the bladder with solutions containing acidophilus bacilli were tried but were not tolerated. The patient is a woman aged 54. Last September she suffered what appeared to be a coronary thrombosis. She was put on absolute bed rest and symptomatic treatment. Weeks went by and she failed to make any improvement. Rather she became progressively weaker. Gastro-intestinal symptoms of anorexia and nausea became prominent. Early in January it was noted that her skin was becoming pigmented. Although her blood pressure had maintained a fairly constant level of 120 systolic 80 diastolic, it was decided to try adrenal cortex extract. Marked improvement immediately followed the institution of treatment. Since the latter part of January she has been receiving daily doses of from 2 to 4 cc. She is now able to be out of bed and can walk short distances about the house. The gastro-intestinal symptoms have largely disappeared and the heart is apparently able to meet ordinary demands. However, the alkaline urine remains a troublesome factor. I should greatly appreciate any information you can give me as to the etiology and treatment of these urologic symptoms. Please omit name and address.

MD Montana

ANSWER.—The progressive weakness, gastro-intestinal symptoms and pigmentation, and the improvement with adrenal cortex extract strongly suggest Addison's disease. In this disease there are occasional cases in which the blood pressure remains at a normal level for a considerable time.

The alkaline reaction of the urine with considerable mucus may be due to a chronic cystitis. Such urine usually contains a varying number of bacteria and a large amount of phosphates. The urine is also alkaline in alkalosis, owing to obstructing gastric lesions or severe vomiting, as well as with alkali therapy. Such an alkalosis can be corrected by administration of ammonium or calcium chloride.

The food intake also influences the urinary reaction. Two or three hours after a meal the acidity is reduced or the reaction may even be alkaline. This is due to the temporary absorption of the acid by the food in the stomach. Proteins tend to produce an acid urine and fruits a neutral or alkaline urine. Sodium or potassium citrate or sodium bicarbonate renders the urine alkaline.

In Addison's disease there is often an achlorhydria, and an increase in the nonprotein nitrogen, urea and sulphates in the blood, which is an indication of renal insufficiency and circulatory disturbance. There may be a creatinuria. The cortical extract exerts a beneficial effect on food ingestion and utilization, so that the achlorhydria and creatinuria usually disappear. There is a disturbance of chloride metabolism, and the patient often craves sodium chloride. Its administration is often very beneficial. The decrease in chlorides may be a factor in causing the alkaline urine.

Impaired renal function with nitrogen retention predisposes to the development of alkalosis as well as acidosis. Frequent alkali reserve estimations should be made in all such cases and the diet carefully regulated.

DANGERS OF LEAD ARSENATE AS SPRAY IN ORCHARDS

To the Editor—Have you any information in regard to symptoms probably resulting from the handling of lead arsenate in spraying orchards over a period of years?

WILLIAM G EYTON MD Newark N J

ANSWER.—The use of lead arsenate for insecticidal purposes has given rise to reports both of lead and of arsenic poisoning. Lead poisoning is believed to be more common than arsenic poisoning. In the manufacture of this agent lead poisoning is fairly frequent while systemic arsenic poisoning rarely arises or at least is rarely diagnosed. In one instance connected with orchard spraying the farmer's residence was situated at the lower edge of a hillside orchard. Currents of air carried some of the spray containing arsenic onto the roof and there deposited it. The farmer made use of cistern water collected off the roof, but only his wife used the cistern water for drinking purposes. In due time she developed a totally disabling disorder diagnosed as arsenic poisoning, and arsenic was found in the cistern water. Hamilton's comment on lead arsenate as found in 'Industrial Toxicology' (Harper and Brothers, 1934) is as follows: "In regard to lead arsenate the curious fact is poisoning often takes the form of lead poisoning, not arsenic, as in a case of Aub's which followed long exposure to lead arsenate used as a spray. This was in a man of forty-two years who had for twenty-seven years worked in the Massa-

chusetts State Forestry Department spraying lead arsenate on trees. During each spraying season he had an attack of colic, then double wrist drop came on which lasted for twelve years before his death from pneumonia, and during the last three years he had had difficulty in walking. At autopsy lead was isolated from the long bones." It is conceivable that lead and arsenic poisoning might coexist or might arise consecutively.

TREATMENT OF SYPHILIS

To the Editor—Please outline the proper treatment for a woman aged 28 who has paralysis of one pupil and 4 plus Wassermann and Kahn reactions. She married at 14 and has been several times pregnant with miscarriages, some due to natural causes some to interference. She was divorced and remarried about one and one-half years ago. The present husband's blood gives a negative reaction. The general examination gave negative results. She has had one course of bismuth treatment and seven neoarsphenamine injections with return of the pupillary contraction to normal. Would the kind and amount of treatment be very different in the case of a person 65 years of age? Please omit name.

MD Connecticut

ANSWER.—Treatment with neoarsphenamine and heavy metals, bismuth or mercury compounds in alternating courses, should be continued for at least a year. In the interim between courses, iodides should be administered. At the end of a year the serum reaction of the blood should be checked and a spinal puncture done to determine whether the case is one of asymptomatic neurosyphilis or an early parenchymatous involvement of the nervous system. Further treatment will depend on the condition of the spinal fluid. In positive cases, tryparsamide should be used or some form of fever therapy. The kind and amount of treatment would be decidedly different in a person 65 years of age. The arsphenamines must be given with great caution in older people with an impaired cardiovascular apparatus.

GLAUCOMA

To the Editor—I have a case of chronic glaucoma with greatly reduced vision in one eye the other being recently enucleated. There is no inflammation and no pain. The pressure varies from 30 to 40 mm of mercury. There is some exudate on the posterior side of the lens which resembles an incipient cataract. The eye recently enucleated showed this exudate to a marked degree yet the inside of the lens did not seem to be affected. The question is: At what pressure will nerve destruction take place? Should the eye be operated on as long as the pressure can be maintained with the aid of mydriatics? Please do not publish name or town.

M D., Oklahoma.

ANSWER.—The amount of intra-ocular pressure as measured by the tonometer is no indication of the necessity for surgery. A numerical value cannot be placed on so-called normal pressure, for normal pressure is that degree which the tissues of the eye can withstand without damage to function. Consequently, repeated examinations of the peripheral visual field, of the central visual field and of visual acuity are necessary to determine whether or not the existing pressure is pathologic for the eye in question. If these functions are damaged by the pressure of from 30 to 40 mm of mercury that pressure is greater than the eye can withstand and surgical intervention is indicated. On the other hand, if there are no losses in the visual fields and the visual acuity remains unchanged, the same pressure is not above the normal range for that eye.

POSSIBLE INFECTION OF ETHMOID SINUSES

To the Editor—A man aged 40 with a right chronic purulent otitis media has had a slight continuous discharge for the past ten years. There is a large central perforation in the drum. Examination of the nose shows a deviated septum to the left with a large polyp probably arising from the ethmoid. Roentgen study with iodized oil shows cloudy ethmoids and maxillaries. The capacity of the maxillaries is 7 to 9 cc of iodized oil. The emptying time is good. What therapeutic procedure is advisable? Please omit name.

MD New York.

ANSWER.—Cases presenting a large central perforation, which usually show no involvement of bone, are seldom proper subjects for aural operation. Even though radical mastoidectomy is performed in some of these cases, suppurative continues in many. As long as there is no bone involvement, there is usually no indication for the radical operation. However, since this type of case often persists because of constant infection by way of the eustachian tube, any nasal or nasopharyngeal infection should be treated. If, therefore, there is evidence of involvement of the nasal accessory sinuses treatment directed toward them is indicated. If there is disease of the ethmoid with polyp formation ethmoidectomy is probably indicated. The use of boric acid alcohol solution in the middle ear by way of the external auditory canal is sometimes beneficial in these cases.

WASSERMANN TEST IN VINCENT'S ANGINA

To the Editor—Kindly advise me whether it is probable that a persistent Vincent's throat (the bacilli and spirilla have been isolated a number of times in the last five months) could produce a positive blood Wassermann reaction. The particular patient I have in mind gives no history that would suggest a syphilitic infection although she has had this persistent Vincent's condition for five months. The literature I have available says that the Wassermann reaction is always negative in Vincent's angina yet I would think that because of its being a spirillum infection over a period of months the bacteria might enter the blood stream and give a positive Wassermann reaction. I would appreciate your opinion or information where I can obtain authoritative literature on the subject.

M D Chicago

ANSWER—The Wassermann reaction is not positive in Vincent's angina. The presence of a positive Wassermann reaction must be attributed to a syphilitic infection and not to the Vincent infection. The fusiform bacilli and spirilla of Vincent's angina are very different from *Spirochaeta pallida* in their pathogenicity and in the lesions produced. It is not to be expected, therefore, that they should produce similar serologic reactions. The books of Kolmer and Kahn on the diagnosis of syphilis discuss the specificity of the Wassermann and Kahn tests.

Perhaps the fact that arsphenamine has great therapeutic value in Vincent's infections as well as in syphilis has led to the incorrect view that Vincent's angina may produce a positive Wassermann reaction. The patient being a woman with history of but little value in excluding syphilis. The positive Wassermann reaction obtained from a competent laboratory is certainly an indication for antisyphilitic therapy, which will also clear up the Vincent's infection in most cases.

OCCIPITAL HEADACHE—HEART MURMURS

To the Editor—Kindly explain if possible the mechanics of (1) occipital headache in intestinal disorders and (2) heart murmur heard only when the patient is in the horizontal position and its significance.

HARRY HALLERMAN, M D, New York

ANSWER—1 We are unable to furnish an explanation of the mechanics of occipital headaches in gastro intestinal disorders. Headaches occur not infrequently in patients with gallbladder disease and duodenal ulcer. Dr. Kleitman of the department of physiology of the University of Chicago in a study of hunger contraction mentioned several years ago the occasional occurrence of headache with retrograde peristalsis in the duodenum. The headache may also be of toxic or migrainous origin.

2 The heart murmurs heard only when patients are in the horizontal position are mostly cardiorespiratory in origin, occurring with cardiac systole by compression of air out of the margins of the overlying lung. They are of no clinical significance and are not heard when the individual is in the upright position, because of lack of the close contact that obtains in the horizontal one.

PLASTIC OPERATIONS ON POSTERIOR PILLARS
AFTER TONSILLECTOMY

To the Editor—A girl aged 16 years, had her tonsils removed several years ago and has a marked scarring and binding down of the posterior pillars on both sides. Resonance is poor. I would appreciate your opinion as to the success of a plastic operation separating the pillars and temporarily suturing in some air silk in an attempt to get some flexibility. The patient has also a colloid goiter. Please omit name.

M D, Texas

ANSWER—Plastic operations of this character are difficult to perform and the results are not always pleasing. They should be undertaken if the patient suffers from marked disability, but the possibility of a poor result should be explained. The operation mentioned might work, but the oiled silk or other material used to prevent the reformation of adhesions would have to be kept in for a week or two.

J. E. MacKenty (Nasopharyngeal Atresia, *Arch. Otolaryng.* 61 [July] 1912) described an operation, which has been valuable in the hands of some. This procedure depends for its success on the formation of palatal flaps in such a fashion that mucous membrane and not raw edges approximate. Dilatation too should be practiced for weeks after.

USE OF HENNA WHITE ON HAIR

To the Editor—I have a patient who has asked me whether or not henna white would harm her hair or scalp. Kindly omit name.

M D Iowa

ANSWER—Henna white is a bleach, varying in composition with various users. One formula, sodium perborate, 18 Gm, henna leaves, 2 Gm., affords an excuse for the name. No other excuse can be seen for the waste of henna leaves. Some use

hydrogen dioxide alone, others make a paste by combining it with magnesium carbonate. Another formula is 68 parts of magnesium carbonate and 32 parts of sodium perborate. This is made into a paste with hydrogen dioxide diluted with an equal quantity of water. All such preparations tend to make the hair brittle. No other harm is done unless loss of the natural color can be called harmful. White henna or henna white is a name used for any bleaching preparation.

REACTIONS TO DIPHTHERIA TOXOID

To the Editor—Is there an increased danger in using the single dose alum precipitated toxoid in children with possible allergy over the usual two dose toxoid? In using the two dose toxoid what is the interval between doses that gives the optimal immunizing effect? Please omit name and address.

M D, Illinois

ANSWER—There is no increased danger in using the single dose of alum precipitated toxoid in children with possible allergy over the usual two dose toxoid.

In using the two dose toxoid the optimal immunizing effect between doses seems to be produced at about monthly intervals. Severe reactions in allergic individuals who have been given alum precipitate toxoid have not been reported.

DINITROPHENOL AND LYMPH GLANDS

To the Editor—I wish to ask whether dinitrophenol will produce hyperplasia and hypertrophy of the lymphatic glandular tissue. A woman came to me who had taken this drug for obesity. The exact quantity she did not remember but at one time she was using fifteen tablets a day. The glandular enlargement involves alone the anterior cervical group bilaterally. The enlargement is pronounced and resembles Hodgkin's disease. This trouble has been present six months and first began two months after the patient stopped the drug. Please omit name and address.

M D Indiana

ANSWER—Dinitrophenol does not produce glandular enlargement as far as is known from published reports. One large series of about 200 patients has been followed without this being observed as a complication. Dogs given three times the therapeutic dose daily for six months show no adenopathy as observed grossly or by microscopic study of their organs. In addition, the drug is probably completely excreted from the body within about three days. All these facts taken together make it extremely unlikely that a glandular enlargement beginning two months after the drug was stopped could have any connection with its administration.

CONVALESCENT BLOOD IN PUERPERAL SEPTICEMIA

To the Editor—In treating a patient with puerperal septicemia, would blood from a patient who has recovered from a similar infection be more beneficial for transfusions? If blood from a cured patient has special antibodies how long would they be likely to remain in the blood stream? Kindly omit name.

M D., West Virginia

ANSWER—There are good reasons to believe that blood from a patient who has recovered from puerperal septicemia would be more beneficial in the treatment of puerperal septicemia than the blood from a person who has not had the disease. It is not possible to say how long the special antibodies may persist in the blood after recovery from puerperal septicemia, but indications are that they may be present at least to some extent for many years.

OBESITY IN CHILDREN

To the Editor—I wish to know the treatment recommended for overweight children between the ages of 8 and 12 whose metabolism is around normal and wish the treatment recommended with thyroid extract and pituitary whole gland and wish to give this by mouth. If the pulse is normal is the treatment perfectly safe if children are at least 15 to 25 pounds (7 to 11 Kg.) overweight for their age? Please omit name.

M D Alabama

ANSWER—The treatment of obese children, normal in other respects, by glandular therapy cannot be recommended. The treatment should be dietary and should be directed at establishing a new and better food habit, so that once the excess weight is lost it does not reappear. The effects obtained with glandular products, when the diet is unchanged, are not only temporary but may actually cause harm by disturbing the normal endocrine balance. With regard to the specific glandular products mentioned, only the thyroid extract has been definitely shown to be effective when taken by mouth. The query does not contain sufficient data to enable one to offer specific dietary advice.

INFECTION OF SEMINAL VESICLES

To the Editor—About one year ago, a man aged 20 came to my office five days after contracting a gonorrheal infection. He had a marked discharge, which persisted for two months. During this time he was taking injections of 0.5 per cent strong silver protein twice daily with much diminution in the amount of the discharge. About three months after the institution of treatment, sounds were passed for two months to prevent stricture formation while injections of 5 per cent silver nucleinate were now used. About five months ago an epididymitis developed which cleared up after two weeks. For the past four months he has been receiving prostatic massage. There is still a slight morning mucoid discharge, and smears are still positive for the gonococci. Is there any other treatment that you could suggest? Please omit name and address.

M D, Pennsylvania

ANSWER.—In view of the fact that the patient had an epididymitis, it is quite evident that the seminal vesicles as well as the prostate gland are involved in the infection. In carrying out prostatic massage sometimes the vesicles are missed and may be responsible for the continuation of the presence of organisms in smears. Massage of the vesicles as well as of prostate gland, followed by an instillation into the prostatic urethra of 0.25 per cent silver nitrate solution, gradually increasing up to 1 per cent, should be repeated about every five days.

SAND BLAST HELMETS

To the Editor—I am surgeon for a large foundry. In the sand blast operation the men are protected by masks made of hardened rubber. The air is purified by passing through water. The question has been raised as to what is the best method of sterilizing these masks after they have been used by one person and before they are put on by another employee.

M D, Ohio

ANSWER.—The U S government, in its specifications for sand blast helmets purchased by its various departments, requires that each article be capable of passing either one of the following sterilization tests

(a) Immersion for ten minutes in a solution of formaldehyde made by placing one part of 40 per cent solution of formaldehyde in nine parts of water, or

(b) Subjection to sterilization by a moist atmosphere of antiseptic gas preferably formaldehyde, for a period of ten minutes, at room temperature.

It has been suggested that care should be taken to remove all the formaldehyde from the masks by washing with water before they are placed in use.

COMPARISON OF BLOOD OF MAN AND ANIMALS

To the Editor—Can you suggest any textbook or periodical references that will deal with the following subjects: A study of the evolution of blood from the simplest circulatory fluid to the highly developed blood of man or a comparative study of the vascular fluids found in all the animals. The textbooks in this library do not cover these subjects at all and I would appreciate your assistance very much.

Librarian, Harper Hospital

JEANNE REEN Detroit.

ANSWER.—The best way to obtain references for these subjects is to look up each phase of the circulatory fluid in each animal and compare it with man. Books on comparative anatomy will give only part of the subject. Data on the formed elements of the blood and their evolutionary history may be obtained from the article by H E Jordan in the *Quarterly Review of Biology* (8 53, 1933) and the monograph by Dr M Hausman (Entstehung und Funktion von Gefässsystem und Blut auf zellulär-physiologischer Grundlage, Basel, Benno Schwabe & Co, 1935).

FALSE POSITIVES IN BENEDICT SUGAR TEST

To the Editor—Will you kindly give me a list of drugs and other substances other than dextrose that reduce copper in Benedict's solution? Please omit name.

M D Massachusetts

ANSWER.—The copper compound in Benedict's solution may be reduced by a number of chemical substances. Chloroform will give a reduction and may be mistaken for sugar. When used as a preservative, it should be removed by heating the urine before testing for sugar. Formaldehyde may also lead to reactions simulating sugar. Boric acid may interfere with sugar determination. Benedict's solution is promptly reduced by alkaloids or the conjugated glycuronic acids. Chloral may also give a reduction.

The first time a urine of any patient shows reduction, further tests are indicated to determine whether the substance is sugar, and the kind of sugar.

Medical Examinations and Licensure

COMING EXAMINATIONS

AMERICAN BOARD OF OPHTHALMOLOGY The Cincinnati examination previously announced will not be held. The next examination will be given in St Louis, Nov 18. Application must be filed before Sept 15. Sec Dr William H Wilder 122 S Michigan Ave, Chicago.

AMERICAN BOARD OF OTOLARYNGOLOGY Cincinnati Sept 14 Sec, Dr W P Wherry 1500 Medical Arts Bldg Omaha.

AMERICAN BOARD OF PEDIATRICS Philadelphia Oct 10 and St Louis, Nov 20. Sec Dr C A Aldrich 723 Elm St, Winnetka Ill.

AMERICAN BOARD OF RADIOLOGY Detroit Dec 12. Sec Dr Byrl R Kirkhn Mayo Clinic, Rochester Minn.

ARIZONA Basic Science Tucson Sept 17. Sec Dr Robert L Nugent Science Hall University of Arizona Tucson. Medical Phoenix, Oct 12. Sec Dr J H Patterson, 826 Security Bldg Phoenix.

COLORADO Denver Oct 1. Sec, Dr Harvey W Snyder 422 State Office Bldg, Denver.

IDAHO Boise Oct 1. Commissioner of Law Enforcement Hon Emmitt Pfister 205 State House Boise.

MINNESOTA Basic Science Minneapolis Oct 12. Sec Dr J C McKinley, 126 Millard Hall University of Minnesota Minneapolis.

MONTANA Helena Oct 1. Sec Dr S A Cooney 7 W 6th Ave., Helena.

NATIONAL BOARD OF MEDICAL EXAMINERS The examination will be held in all centers where there are Class A medical schools and five or more candidates desiring to take the examination Sept 16-18. Ex. Sec, Mr Everett S Elwood 225 S 15th St Philadelphia.

NEW HAMPSHIRE Concord Sept 12-13. Sec. Board of Registrars in Medicine Dr Charles Duncan State House Concord.

NEW YORK Albany Buffalo New York and Syracuse, Sept. 16-19. Chief, Professional Examinations Bureau Mr Herbert J Hamilton 315 Education Bldg Albany.

OKLAHOMA Oklahoma City, Sept 10-11. Sec, Dr James D Osborn Jr, Frederick.

PUEBLO Rico San Juan, Sept. 3. Sec. Dr O Costa Mastry Box 536 San Juan.

RHODE ISLAND Providence Oct 3-4. Dir Department of Public Health, Dr Edward A McLaughlin 319 State Office Bldg Providence.

WISCONSIN Basic Science Madison Sept 21. Sec., Professor Robert N Bauer, 3414 W Wisconsin Ave Milwaukee.

New York January Examination

Mr Herbert J Hamilton, chief, Professional Examinations Bureau, reports the written examination held by the New York State Board of Medical Examiners in Albany, Buffalo, New York and Syracuse, Jan 28-31, 1935. The examination covered 9 subjects. An average of 75 per cent was required to pass. Two hundred and twenty-nine candidates were examined, 175 of whom passed and 54 failed. The following schools were represented:

School	PASSED	Year Grad	Number Passed
University of Arkansas School of Medicine	(1932)	(1934)	2
George Washington University School of Medicine	(1934)	(1934)	1
Georgetown University School of Medicine	(1934, 2)	(1934, 2)	2
Howard University College of Medicine	(1934, 3)	(1934, 3)	3
Emory University School of Medicine	(1934)	(1934)	1
University of Georgia School of Medicine	(1932)	(1932)	1
Loyola University School of Medicine	(1934, 2)	(1935)	3
Rush Medical College	(1934)	(1934)	1
School of Medicine of the Division of the Biological Sciences	(1934, 2)	(1934, 2)	2
University of Illinois College of Medicine	(1934)	(1934)	1
University of Louisville School of Medicine	(1932)	(1932)	1

Nevada May Examination

Dr Edward E. Hamer, secretary Nevada State Board of Medical Examiners, reports the oral and written examination held in Carson City May 6-8, 1935. The examination covered 11 subjects and included 110 questions. An average of 75 per cent was required to pass. Two candidates were examined, both of whom passed. Four physicians were licensed by reciprocity. The following schools were represented:

Book Notices

Stammering and Allied Disorders By C S Bluemel M.A. M.D.,
F.A.C.P. Cloth Price \$2 Pp 182 New York Macmillan Com
pany 1935

This is a splendid discussion by one of the keenest students of stuttering. Allied disorders are mentioned only to aid in understanding the nature and cause of stuttering. The term "stuttering" is preferable to "stammering," since the latter is used in several different senses. Bluemel divides stuttering into two types: primary, or basic, and secondary. Primary stuttering is regarded as due to a physiologic clash between the speech response, whether viewed, following Pavlov, as a conditioned (author's preference) or unconditioned reflex, and temporary or intermittent inhibition that obstructs it, with resulting secondary emotion. Total inhibition produces mutism. Inhibition is defined as a physiologic function that checks the conditioned reflex. It may affect inborn as well as conditioned responses. Although Bluemel insists that emotion is not the basic cause of primary stuttering and that physiologic inhibition can explain almost all the mysteries of primary stuttering, he fails to mention that in Pavlov's experimental work with animals it is most probable that a state of excitement, interest or expectation is aroused and is responsible for the so-called positive conditioning, while its absence occurs in negative conditioning. He fails to define the term "emotion" as he uses it. If he agrees to its definition as an excited state of the total animal machine (both "mind" and "body"), then the causes for inhibition enumerated by him (excitement, overstimulation, fatigue, illness, shock) produce emotion.

Secondary stuttering depends mainly on associative or so-called conditioned inhibition, resulting from negative conditioning to words, letters, persons and situations, and also leads to associative emotional responses. The symptoms (abnormal respiration, unwonted physical effort in speech, the use of starters, wedges and synonyms, embarrassment, self-consciousness, confusion, fear, inferiority feelings, hypersensitive social attitudes) are attempts by the stutterer to escape his predicament and are but complications of primary stuttering. Although he states that the two types may coexist and that secondary "does not necessarily" replace primary stuttering, he does not deny that it may. Of course, if it does, emotion per se could be responsible for stuttering.

The principles of treatment are enumerated as (1) tranquilization (by rest, isolation, sedatives, calming atmosphere) to minimize the effects of inhibition at the onset of stuttering; (2) reinforcement of the conditioned speech response in various ways (by reading to the patient, speaking in unison, pronouncing difficult words for him when in speech distress, both alone and in class); (3) unconditioning by whispered speech, drawing speech, blindfolding during speech, and (4) extension of these ideas to as many environmental speech situations and as continuously as possible. Primary stuttering he regards as curable in most cases, but secondary stuttering less so especially in confirmed adult stuttering. The author admirably discusses other current views only to show their unsoundness.

Although it has been written primarily for teachers, stutterers and parents, no one seriously and scientifically interested in stuttering should fail to study this book. It is indeed a valuable contribution to the literature on this important problem.

Manchurian Plague Prevention Service Memorial Volumes 1912-1932.
Edited by Wu Lien Teh Director National Quarantine Service. Cloth
Pp 469 with illustrations Shanghai National Quarantine Service 1934

The delegates who attended the ninth Congress of the Far Eastern Association of Tropical Medicine at Nanking in October 1934 received this handsome memorial volume recording the work of the Manchurian Plague Prevention Service for the two decades of its functioning under Chinese auspices under the able direction of Dr. Wu Lien-Teh. The Japanese occupation of Manchuria has shifted the direction since 1932 into other lands.

The wide distribution of plague as the result of the last pandemic, not only in the tropics but also in temperate zones, and the fact that the pneumonic form was prevalent in man in

the winter months in Manchuria, both serve to create a basis for a general interest in the subject among physicians throughout the United States. Added reasons for such interest lie in the facts that in man the pneumonic form of plague is generally fatal is accompanied by coughing, and is spread by droplet infection in cold climates. Hence no insect vector, such as the rat flea, is directly involved, and no mammalian reservoir host, such as the rat, is necessarily concerned at all throughout the period of a human holocaust. The rodent reservoir host is, however, the background in which continuously lurks the ever imminent danger of the flare of pneumonic plague in man. It is for this reason that the invasion of sylvatic plague among the ground squirrels of the foothills of the Sierras and Cascade Mountains creates a widening menace in the United States.

The sequence of events in the epidemiology of the pneumonic form of the plague in Manchuria was as follows: 1. Deaths by plague (of the pneumonic type in experimental rodents) occurred among the Tarabagan or Siberian marmot, *Arctomys bobac*, extensively collected for its fur, which is used as a substitute for Russian sable. 2. The migrating young of the year may enter old burrows, the former inmates of which died of the plague, and they also may acquire the infection and die in their burrows. Other rodents in Manchuria also die of the plague. 3. Chinese coolies from Shantung and elsewhere to the number of 10,000 visit the marmot territories from August to October, collect the skins, and often dig the marmots out of their burrows and may eat their flesh. These trappers gather in the Manchurian centers of the fur trade from October to November in crowded, insanitary quarters with their (in some instances) germ-laden skins, and, when the sales are made, return to their homes in China. This sets the stage for the tragedy that follows.

In the two major epidemics of pneumonic plague in Manchuria of 1910-1911 and 1920-1921 there were sporadic cases of bubonic plague in August, with the subsequent appearance of the pneumonic type in October, followed by the rapid spread of this form of the disease as the trappers exposed to infection from the rodents streamed back to their homes. Persons exposed to droplet infection from human cases scattered from each center after the first death, unless restrained by the authorities in their efforts to isolate those who had been thus exposed. The rapid course of the disease, the ignorance and terror of the people, and the violence of the soldiery made control doubly difficult. The exclusive operation of human agency by droplet or other contagion is emphasized by the fact that not a single case of rat plague was detected in 13,000 rats examined in cities in which the human pneumonic plague was at the time in full swing. Toward the close of the epidemic, human cases of pulmonary (septicemic) type tend to increase in number.

Dr. Wu cites the prevalent opinion that the rodent disease has long been known among the Manchurian peasantry and the trappers, and that they usually expected the disease among men to run its course and die out. Occasional cases of bubonic and even of pneumonic plague came to record in Manchuria or Siberia between 1911 and 1921 but no great epidemic developed in that interval. The reservoir of rodent plague did not overflow in the interval, as in the years of the two epidemics.

The physicians of the United States should be aware that sylvatic plague is established in this country among the rodents, as it is in Manchuria. The California ground squirrel (*Citellus beecheyi* Richardson) and the Oregon ground squirrel (*Citellus oregonus* Merriam) harbor the infection, for which their fleas are the insect transmitters. Fortunately the centers of plague infection, as far as known, are few and have been closely watched by the federal and the California state authorities. Two new centers have, however, appeared in the past summer with devastation of the local rodent populations, both in regions with a sparse human population. Only a single human bubonic case occurred in each of these rodent areas, one of which was chronic. It is obviously the duty of the federal authorities to see to it that this situation does not get out of control for lack of adequate and thorough inspection.

This memorial volume of Dr. Wu's gives the detailed history of the two Manchurian outbreaks, the microscopic appearance of the lesions, the pathologic changes and the clinical symptoms. There is also a study of insect transmission among rodents, a list of known rodent hosts and of the parasites of these hosts, and discussions of the perpetuation of the plague among rodents and of the "original home" of the plague. Some account of the work of the Plague Prevention Service on cholera and in other fields is also included in the book.

Dr. Wu has rendered a great service to the cause of preventive medicine by his presentation in English of the scattered data in the Chinese reports on these two disastrous epidemics of the most dangerous form of the plague. His book makes it clear that rat control can by no means be trusted to serve as a protection from the invasion of plague in its worst form.

Mental Health: Its Principles and Practice, with Emphasis on the Treatment of Mental Deviations. By Frank F. Howard, Ph.D., Professor of Education and Psychology, Middlebury College, and Frederick L. Pauly, M.D., Psychiatrist, State Education Department, University of the State of New York. Cloth. Price \$3.50. Pp. 551 with 14 illustrations. New York and London: Harper & Brothers, 1935.

Mental Health is a somewhat misleading name for this book, as the subject matter is mainly concerned with the contributions of psychiatry to the understanding and management of educational problems. The book is similar to the volume of Anderson on Psychiatry and Education and the volume of Bassett on the School and Mental Health. It differs from previous similar attempts to correlate the fields of education and psychiatry in that the approach is entirely that of the psychobiologic school of Meyer. The book might have been called Educational Psychobiology. This clear and forceful presentation of the credo of the psychobiologists is welcome, for previously there was no handy epitome of this significant point of view.

The pluralistic approach to psychiatric problems with its emphasis on the behavior of the total human organism appeals to the unprejudiced reader as a form of sound eclecticism. The insistence of the psychobiologist that he refuses to be strait-jacketed by any single school of thought or practice which presumes to hold the key to exclusive salvation should be placed before scientific assemblies to remind them that propagandism and fanaticism have no place in scientific research. The cacophonous terminology of objective psychobiology has not yet been accepted by psychiatrists in spite of the widespread adherence to the fundamental tenets of Meyer's teachings. The classification of the psychoses and neuroses, therefore, is the least commendable part of this interesting work.

After a rather long introduction and exposition of the psychobiologic teachings and a review of the principles of modern psychopathology, including mental mechanisms, the authors discuss the specific problems of the school child. The criticism of the emphasis on the intellect in the school system and the urging of greater attention to training of character, personality, emotional attitudes and the individual's total reaction to reality is no longer a cry in the wilderness. The role of conative and affective factors in performance is being emphasized in all recent educational programs. The specific suggestions for reconstructing personality and handling deviations in child behavior are worthy of study. The psychobiologic balance chart, which will permit adequate records of the psychologic development of pupils physically, intellectually, emotionally and socially, is a worthy attempt to formulate some practical plan of gathering the necessary data for a more fundamental understanding of the nature of mental illness.

The chapter on the visiting teacher, who is a sort of liaison officer between the school and the other institutions that modify and influence the pupil's behavior, should be read by every psychiatrist. The classification of children's behavior disorders and the outlines for case studies contain invaluable data for clinical organization. The group of concrete illustrations on page 331 of the personality twists and shortcomings of professional people is an unusually rich fragment of descriptive psychiatry. The Peyser plan for character building and prevention, Miss Farrell's classic work on the education of mental defectives and the review of the child guidance movement are all worthy of the attention of every medical practitioner and student.

The volume is essentially addressed to laymen and occasionally a certain amount of oversimplification is evident, perhaps for pedagogic purposes. The repeated emphasis on the unquestionable role of bad habit in the etiology of the psychoses and neuroses strikes one as rather dogmatic. The statement on page 259 that "the possibility of recovery of schizophrenia is conditioned almost entirely on its early detection and proper treatment by a skilled psychiatrist" will be challenged by many. The authors obviously fail to place the proper emphasis on the role of subconscious constellations as determinants of human behavior. This decided stress on the role of the environment in causing behavior disturbances is perhaps a necessary check on some of the recent unbridled tendencies to disregard the role of such exogenous factors.

It would be well to banish the term insanity from a textbook of this type unless problems of responsibility are discussed from the legal standpoint. The text is readable, though there is a great deal of repetition. The use of some obsolete words, such as labileness, imaginal and frustrantous, impairs the clarity of the text. The authors failed to mention the role of pernicious anemia in accounting for the mental symptoms of a woman whom they discussed on page 70. The reports of neurologic examinations of the cases presented in detail need revision. The reaction of pupils to light and in accommodation does not belong under the second cranial nerve. Convergence is not a function of the optic nerve. The division of the examination of cranial nerves into anterior, middle and posterior hindbrain segments is confusing and has no clinical value.

Thérapeutique médicale. VIII. Système nerveux. Par M. Loeper. Avec la collaboration de Alajouanine et al. Paper. Price, 50 francs. Pp. 379 with 21 illustrations. Paris: Masson & Co. 1935.

The first portion of this book, by Loeper, deals with general therapeutics, including a study of nerve sedatives, hypnotics, analgesics, anesthetics and tonics. He considers bromides, valerian and borax sedatives to the general nervous system, and the drugs of the atropine series mesencephalon sedatives because of their value in parkinsonian tremor, which is not affected by the first mentioned group. The term "sympathicolytic" is proposed for sedatives of the sympathetic nerve system, and under this heading are classified ergotamine, yohimbine and crataegus. The belladonna series is spoken of as "para-sympathicolytic" (why not "vagolytic") in contrast to the sympathicotonic epinephrine and ephedrine and the vagotonic physostigmine. Among the general anesthetics, evipal is given a rather special discussion, which it probably deserves. Under hypnotics, the synergism of trional and paraldehyde, and of opiates with chloral is emphasized, so is the increase in analgesic value of the combination of coal tar analgesics with barbiturates. The special therapy of diseases of the nervous system is discussed by a number of specialists, in "whose conscientiousness and competence" the editor-in-chief has confidence. In the discussion of apoplexy, Alajouanine mentions statistics of Forx, according to which cerebral softening is four times as frequent as hemorrhage and partial obliteration of the blood vessels twice as common as total obliteration. Mollaret classifies the various methods of pyretotherapy according to therapeutic value in diseases of the nervous system as follows: malaria therapy, short wave electropexia, then fever induced by sulphur in oil and lastly that excited by intravenous vaccine administration. It finds its chief place in syphilitic diseases of the nervous system and is of doubtful value and even harmful in most others. In the treatment of epilepsy, Pagniez lists phenobarbital as the remedy first in value, provided it is given in sufficient dosage and without interruption. When cerebral hypertension is suspected, concludes Lemaire, the tension of the cerebrospinal fluid should be measured and differentiation made between free and block-d hypertension. Decompression by lumbar puncture must be performed slowly, to avoid bulbar block. Osmotherapy is of doubtful value; massive venesection is more valuable in acute conditions. In chronic cerebral hypertension due to tumor, operative decompression should be undertaken before vision is much damaged, if radiotherapy fails. The localization of cerebral tumors and subsequent operation should be undertaken promptly, emphasizes Martel. Radiotherapy should be considered merely a treatment for cranial

hypertension due to cerebral tumors rather than for the tumors themselves, says Hagenau, in a special chapter devoted chiefly to the roentgenologic technic. In the treatment of migraine, Vallery Radot attempts to differentiate various etiologic forms endocrine, digestive, biliary, allergic and cervical neuritis from a group of migraines of indeterminate origin. The book concludes with a chapter on the electrotherapy of pain by Delhern, on psychotherapy by Cadet, and on balneotherapy and climato-therapy by Villaret.

Diseases of the Heart. By John Cowan B.A. M.D. D.Sc. Consulting Physician Royal Infirmary Glasgow and W. T. Ritchie O.B.E. M.D. F.R.C.P.E. Professor of Medicine and of Clinical Medicine Edinburgh University. With a chapter on The Ocular Manifestations of Arterial Disease by Arthur J. Ballantyne M.D. F.R.F.P.S. Lecturer on Ophthalmology University of Glasgow. Third edition. Cloth Price \$9. Pp 632, with 335 illustrations. Baltimore: William Wood & Company 1935.

In 1914 Cowan published his work on the heart. The second edition with Ritchie as co author appeared twelve years later. These volumes received and deserved commendation. They were popular as textbooks for undergraduates and were useful to practitioners. The third edition merits the success of its predecessors. The many advances in knowledge of heart disease of the last twenty or even twelve years have necessitated much revision and much in the way of addition. The arrhythmias, the electrocardiogram, bacterial endocarditis, coronary thrombosis and angina pectoris are some of the topics that have been expanded and brought down to the present. Anatomy and pathology are adequately discussed. Mention should be made of the excellent character of the illustrations, nearly all of which are original. There is a helpful chapter by Arthur J. Ballantyne on the ocular manifestations of arterial disease. Fortunately the authors in their enthusiasm over the x-rays and the electrocardiograph have not forgotten the stethoscope and percussion. Valvular diseases are still deemed worthy of consideration, the murmurs are diagrammed and physical diagnosis not slurred over as out of date. The book is one that may be warmly recommended to the practitioner or undergraduate as scientific, practical and trustworthy.

Traité de pathologie médicale et de thérapeutique appliquée. Publié sous la direction de Emile Sergent professeur de clinique médicale propédeutique L. Ribadeau-Dumaeu médecin de la Salpêtrière et L. Babonnel médecin de St Louis. Tome XXXII. Radiologie. Fascicule 2. Radiothérapie rayons x—radium. Par Paul Cottenot médecin électro-radiologiste de l'Hôpital Broussais et Simone Laborde chef du service de curiethérapie à l'Institut du Cancer. Second édition. Papier. Price 70 francs. Pp 514 with 80 illustrations. Paris: Norbert Maloine 1934.

Students and practitioners of radiotherapy will find in this volume a satisfactory and scientifically accurate description of the physical properties of the x-rays and the armamentarium and technical information necessary for their application to the treatment of disease. A section of the book concerns the physical properties of radioactive substances and the instrumentation and technical details of application of curie therapy. A third section deals with the biologic action of roentgen rays and the radiations from other radioactive substances, their effects on normal and pathologic tissues, and their application to various pathologic states. The latter are classified according to systems in the classic manner. More than a hundred pages or one fifth of the book, is devoted to the treatment of malignant disease. A chapter on protection for patient and operation concludes. The details and methods concerning the various lesions are in keeping with methods generally accepted, but much is included that belongs to the history of the past and has been discarded in the practice of today.

The units of measurement of x-ray dosage are discussed and compared. Many American readers of abstracts of French articles on radiotherapy do not appreciate that the French unit R has a smaller value than the international unit r. The R devised by Solomon represents the quantity of x-radiation that liberates by ionization in a small ionization chamber the same quantity of electricity that is liberated in a second in the same chamber by a gram of radium placed 2 cm from the axis of this little chamber, the radium rays being filtered through 0.5 mm of platinum. The international unit r adopted by the International Congress of Radiology in Stockholm in 1928 is equal in value to 2.2 R (Solomon).

The work is a practical handbook of current knowledge up to within a fairly recent date. The practice is also that currently approved in most of the larger hospitals.

Know Thyself. A Study in Mental Qualities. By John Potts M.D., D.C.L. Cloth Price \$3. Pp 267. Philadelphia: Dorrance & Company Inc. 1935.

This seems to be an effort to make every one into a psychologist. The author promulgates a hundred rules for evaluating the minds of those with whom the reader may come in contact. He seems distressed by the prevalent human tendency toward wishful thinking and toward making excuses for failures. He divides minds, apparently to his own complete satisfaction, into three groups: superior, mediocre and inferior. The ideas expressed in 250 pages of tedious and repetitious platitudes could readily have been condensed to one-third the verbiage. One cannot escape the impression that any one who takes the book seriously and goes about applying the hundred rules to his friends will soon become an insufferable intellectual snob. Despite the obvious sincerity of the author and the presence in the book of much useful information, the work can scarcely be recommended as a significant contribution to the popular literature on mental hygiene.

Clinical Science Illustrated by Personal Experiences. By Sir Thomas Lewis C.B.E. F.R.S. M.D., Physician in Charge of Department of Clinical Research University College Hospital London. Department of Clinical Research University College Hospital London. Cloth Price 12s. Pp 189 with 49 illustrations. London: Shaw & Sons Ltd. 1934.

Sir Thomas Lewis is generally looked on as a laboratory worker. That he has also been in touch with the patient is shown by his early publications, *Clinical Disorders of the Heart Beat* and *Clinical Electrocardiography*. His later volume on *Diseases of the Heart* is further evidence that the author of *Mechanism and Graphic Registration of the Heart Beat* is interested in clinical medicine as well as in laboratory research. Of late Sir Thomas has been emphasizing the need of scientific investigation in hospitals of problems presented by phenomena of disease that are not yet clearly understood. This work demands concentrated study on the part of men who are not alone practitioners but who are also trained in the technic and imbued with the scientific habits of thought of the laboratory worker. This volume has as its major motive the stimulation of competent men to work of this character. The scope and methods of this "clinical science" are considered in the first chapter of the book. This chapter may be regarded as a sermon based on the text presented by the original observations and experiments described in the remaining chapters. These chapters—the same is true of the first one—consist largely of articles previously published. They are more than reprints, however. They are rewritten, often condensed, and stripped of distracting references to authorities or to conflicting theories. Among the topics considered are auricular fibrillation, auricular flutter, capillary pulsation, axon reflexes in man, muscular pain in intermittent claudication, anginal pain and Raynaud's disease. It is surely a cause for congratulation that workers in medicine may have these articles brought together in such convenient form, revised and edited by Sir Thomas himself. The practitioner too, though he may not plan to be an investigator in "clinical science" will enjoy and profit by the reading of this volume, for it is needless to add that when Sir Thomas Lewis writes he has something to say and that he says it forcefully, concisely and clearly.

Common Sense for Mothers on Bringing up Your Children from Babyhood to Adolescence. By Mrs. John S. Reilly. With an introduction by Charles Gilmore Kerley M.D. Cloth Price \$2. Pp 380 with illustrations. New York & London: Funk & Wagnalls Company 1935.

This book is divided into five parts: a discussion of babies, toddlers, school age children, adolescent boys and girls, and some common sense suggestions for mothers. The many problems that arise in caring for children are discussed in a personal, friendly manner. The author believes that the mother should have a dominant position in the home in the training of the children. She discusses the everyday problems, familiar to all mothers, emphasizing especially feeding, sleeping, clothing, preschool difficulties and the modern problems of the adolescent boy and girl. She asserts that there should be close

association between the parents and the children, and points out that the rewards in motherhood are many. The section relating to the school age and adolescence are unique and will aid parents in solving many of the perplexing questions that arise at this time of the child's life. The book will be found valuable to all parents.

Experimental Studies on Cancer I The Influence of the Parenteral Administration of Certain Sugars on the Growth of Malignant Tumors By Carl Voegtlin R. H. Fitch Herbert Kahler J. M. Johnson and J. W. Thompson II The Estimation of the Hydrogen Ion Concentration of Tissues in Living Animals by Means of the Capillary Glass Electrode By Carl Voegtlin Herbert Kahler and R. H. Fitch III The Influence of Hydrogen Ion Concentration upon the Reversal of Proteolysis in Oxygenated Extracts of Normal and Neoplastic Tissues By Mary L. Mayer J. M. Johnson and Carl Voegtlin IV A Comparison of the Growth of the Jensen Rat Sarcoma in Subcutaneous and Intramuscular Transplants By W. R. Farle and Carl Voegtlin Prepared by direction of the Surgeon General U. S. Treasury Department Public Health Service, National Institute of Health Bulletin No. 164 January 1935 Paper Price 10 cents Pp. 58 with 8 illustrations Washington D. C. Supt. of Doc. Government Printing Office 1935

This pamphlet contains four articles on the results of studies on various problems relating to cancer.

Medicolegal

Dental Practice Acts Statutory Restrictions on Advertising Upheld, Regulatory Power of Board—The Modern System Dentists, Inc., the New System Dentists, Inc., and the Parks Painless Dentists, Inc., apparently engaged in the practice of dentistry in Wisconsin, sought to restrain the Wisconsin board of dental examiners from enforcing certain rules adopted by the board with reference to dental advertising. The trial court sustained a demurrer interposed by the board, and the plaintiffs appealed to the Supreme Court of Wisconsin.

The dental practice act of Wisconsin provides that the term "unprofessional advertising," as used in the act, shall include (1) advertisements containing untruthful, impossible, deceptive or misleading statements, (2) the advertising of professional superiority, (3) the advertising of fixed prices "when the nature of the service rendered and material furnished must be variable," and (4) advertising by means of large, display, glaring, illuminated or flickering light signs or signs which contain the representation of a tooth, bridge work or any portion of the human head. The act authorizes, furthermore, the board of dental examiners to adopt reasonable regulations pertaining to unprofessional advertising as defined in the act.

The statutory restrictions on advertising were upheld, the court basing its holding on the reasoning of the Supreme Court of Oregon in *Scimler v. Oregon State Board of Dental Examiners*, 34 P. (2d) 311 (55 Sup. Ct. 570) abstracted in THE JOURNAL, June 1, page 2025, in which case the constitutionality of similar statutory provisions in the Oregon dental practice act was upheld. The Wisconsin act, said the Supreme Court of Wisconsin, does not deprive the plaintiffs of property without due process of law. If their practices are in the judgment of the legislature detrimental to the health, morals and welfare of the state, their activities may be restrained in the manner attempted by the dental practice act.

The board, purportedly acting under statutory authority, promulgated certain rules relative to advertising which the plaintiffs contended were invalid. The board declared that the following form of advertising tended to deceive or mislead the public, within the meaning of the act:

- (a) The advertising of particular services or appliances at a price From \$—— Dollars up or wording to that effect.
- (d) Signs of dentists used in any other place except on the premises of the building in which the office is located.

Another rule promulgated by the board provided:

Rule 5. It is the opinion of the Board that the nature of professional services rendered and materials required vary in each instant case and that the advertising of any fixed price for any particular operation or work is in violation of 152.06. (c) which provides Advertising definite fixed prices when the nature of the professional services rendered and the materials required must be variable.

The legislature, in the opinion of the court having defined "unprofessional advertising," the power of the board was limited in that respect to a ruling as to what does and does not come within the statute and to amplifying and defining the terms used therein. The board ruling providing that advertising particular services or appliances at a price "From \$—— Dollars up" tends to deceive or mislead the public was held to be clearly within the power of the board to adopt. On the other hand, the board had no authority to adopt the rule prohibiting the use of a sign in any place other than on the premises of the building in which the dentist's office is located, because, while the dental practice act restricts the contents of signs, it is silent concerning the place where the sign may properly be placed, whether on an office door, wall, billboard or in a news paper. The validity of the rule providing that the nature of professional services is such that all dental services rendered and materials furnished are variable was upheld. This involved, in the opinion of the court, a matter of expert knowledge about which the members of the dental board were much better informed than any one outside the profession could possibly be. It may be argued, said the court, that from the language of the statute itself it follows as a necessary implication that there are some services and some materials which are not variable. That is a matter, however, on which the legislature had no more information than other laymen and they quite clearly left it to the board of dental examiners to determine that matter as a question of fact. Likewise, a rule relating to the size of advertisements and the maximum size of letters to be used thereon was upheld.

Since some of the regulations adopted by the board were not authorized under the dental practice act, the Supreme Court held that the complaint stated a good cause of action and that the trial court erred in sustaining the demurrer interposed by the defendant board. The case was therefore remanded to the trial court with directions to overrule the demurrer—*Modern System Dentists Inc. et al v. State Board of Dental Examiners of Wisconsin (Wis.)*, 256 N. W. 922.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to THE JOURNAL in continental United States and Canada for a period of three days. Periodicals are available from 1925 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

*New and Simple Method of Avoiding High Resistance and Overshooting in Taking Standardized Electrocardiograms J L Jenks Jr Cambridge Mass. and A Graybiel Boston —p 693

Arteriosclerotic Heart Disease and Chronic Congestive Failure—Nemet and Gross studied the factors that are responsible for the development of chronic congestive failure in chronic coronary disease and myocardial fibrosis. The clinical and postmortem records of 100 unselected cases were studied. The majority were in or gave a history of, congestive failure. Varying degrees of vascular and myocardial damage were common to the entire series, but the majority of patients with congestive failure had definite and in most instances advanced cardiac hypertrophy. There were but three exceptions to this rule. The group not in failure had nonhypertrophied or, in a few cases, slightly hypertrophied hearts. The characteristic feature of the chronic congestive phase of chronic coronary artery disease is the presence of cardiac hypertrophy. Increased initial fiber tension rather than increased work is the stimulus for generalized cardiac hypertrophy. Contraction with increased initial tension compensates for inadequate contractility. Myocardial disease by diminishing contractile power calls forth increased initial fiber tension and may according to the theory be the cause of generalized cardiac hypertrophy. The application of this concept is not sufficiently supported, however, by clinical experience. The data in the literature are contradictory on this point. The authors' opinion is that in the majority of cases generalized and advanced cardiac hypertrophy is caused by hypertension present or antecedent, and not by vascular and myocardial damage. Diminished blood supply and severe muscle damage produce loss of contractility and may cause failure without leading to fiber hypertrophy. The striking predominance of hypertrophied hearts of the group in failure however, indicates that it is work under long standing increased fiber tension irrespective of the cause, and the eventual loss of contractile power of the hypertrophied fiber that lead to chronic congestive failure. Congestive failure in

chronic arteriosclerotic heart disease is—like that of other types of heart disease—overwhelmingly the failure of the hypertrophied heart

Method of Taking Electrocardiograms—To avoid distortion in taking standardized electrocardiograms it seems to Jenks and Graybiel necessary to provide an electrode which will not polarize even in the presence of moderately high skin resistance, or to adjust the damping of the string to prevent in part the overshooting or to reduce the skin resistance to consistently low values. Experiments were made with a view toward lowering sufficiently the natural impedance to electric currents found in the skin, thus permitting the use of a high frequency string of low resistance. By this procedure there would also be the added advantage of minimizing the effects of outside vibration. During the course of experimentation a combination of substances which gave unexpectedly good results was discovered, and it was found possible to include the requisite substances in the form of a paste. By the use of this paste, patients from whom it was previously impossible to obtain satisfactory electrocardiograms now yielded complexes of correct form and amplitude. Although the chief purpose of the paste is to reduce skin resistance, it was also found to form an excellent nonpolarizing contact between the skin and the electrode. The mixture contains $6\frac{1}{2}$ pounds of sodium chloride, 8 pounds of pumice (powder), 8 ounces of gum tragacanth, 4 ounces of potassium bitartrate, 24 ounces of glycerin, 1 ounce of phenol (carbolic acid) and 2 gallons of water. The gum tragacanth and glycerin are heated in half the volume of water for six hours. The potassium bitartrate and sodium chloride are dissolved in the remaining volume of water and added. The resulting mixture is stirred thoroughly with an electric mixer and heated again for an hour. The phenol and pumice are now added, together with more water if necessary, and the whole mixture is again mixed until it is of a creamy consistency. In actual use a small quantity of the paste is rubbed briskly on the desired skin area, a small surplus being left to facilitate contact with the electrode. The electrode, a german silver plate measuring about 5 by 8 cm., is firmly applied over this area and held by means of an elastic ribbon or band. Within reasonable limits, the size of the electrode is immaterial so far as the resistance of the skin and polarization of the electrode are concerned. Resistance measured on the electrocardiograph, using the electrodes and paste described, is in most cases about 1,000 ohms and rarely as high as 2,000 ohms. This applies equally to myxedematous, cachectic or Negro patients, from whom it is sometimes difficult or impossible to obtain satisfactory tracings. Electrocardiographic tests made on about 400 patients showed uniform results, with resistances of from 1,000 to 2,000 ohms and no overshooting.

Treatment of Scurvy with Cevitamic Acid—Goettach gave cevitamic acid intravenously to four infants having severe scurvy long enough for comparison with control patients receiving orange juice. Calcium was deposited in subperiosteal

hematomas on the second, third, fourth and fifth days, respectively, while in the control infants who received orange juice calcification was not noted until the eighth, tenth and eleventh days. Initial roentgenograms taken before therapy was instituted in six cases showed no evidence of subperiosteal hemorrhages of the long bones, while in the remaining two slight calcification of such hematomas could be seen. The clinical condition of the latter infants prevented further maintenance in the hospital on a scorbutic diet to corroborate the histories obtained on admission. In each case the diet consisted of boiled milk only, and no specific antiscorbutic substance had been added for at least one month prior to admission. In one patient initial roentgenograms revealed definite calcification of small subperiosteal hemorrhages of the lower extremities, but none in the upper extremities. Four days after cevitamic acid had been given an extremely large subperiosteal hematoma of the left humerus was outlined by newly deposited calcium, while only a slight increase in density had occurred in the hematomas of the lower extremities. The spectacular increase of density in the hemorrhage cloaking the humerus was never matched by similar changes in the hematomas of the tibias. From the point of view of relief of subjective symptoms, treatment with cevitamic acid resulted in satisfactory clinical improvement and was at least as effective as treatment with orange juice. In three babies who received cevitamic acid, pain was apparently relieved more quickly than in the controls. In no infant was pain relieved immediately, even when the massive dose of 400 mg of cevitamic acid was given intravenously. No untoward reaction followed intravenous therapy, in spite of the fact that the acid was not neutralized before injection. The tourniquet test was not found reliable as a measure of healing of the scorbutic process in infants.

Calcium Deficiency in Childhood—Nesbit describes a syndrome of increased neuromuscular irritability and functional imbalance occurring in infancy, which is strikingly relieved by measures that improve the absorption of calcium. Thirty-six cases illustrate the relation of the syndrome to convulsions and functional disturbances occurring in later childhood. These cases portray a symptom complex manifested (1) in early infancy by hypertonia, restlessness, excessive crying, retraction of the head, irregular respirations, bronchospasm, enterospasm, pyloric spasm, convulsions and spells of cyanosis, (2) in the runabout period by sleeplessness, extreme restlessness, syncope and convulsions, and (3) in the school period by hypertonicity, emotional instability and incorrigibility, together with other symptoms of increased neuromuscular irritability and chorea. The frequency of emotional upsets, excessive apprehensiveness, sleeplessness and tremor in the mothers of children having these symptoms has been demonstrated. The prompt relief afforded by calcium therapy in each of the instances cited encourages one to attribute the underlying cause to some error in mineral metabolism.

Allergic Eczema.—Among about 400 cases of eczematous eruption studied in the allergy division of the dermatologic clinic in the last six years, Hopkins and Kesten were able to find seventy-five in which the evidence seemed definite that food was either the sole cause or a contributing cause of the dermatosis. Food was the sole cause in two thirds and a contributing cause in one third of the cases. More than two thirds of the patients were children. The most striking clinical characteristic of food eczema is the distribution of the eruption. The similarity is remarkable among patients in each age group. Equally striking are the changes both in distribution and in character that mark the progress of the disease. Patients with food eczema often present other symptoms of food allergy and of allergy to other substances, the frequency of which is shown. In forty patients there was a history of allergic disorders among the patient's relatives. There was no special frequency of eczema as compared with asthma and hay fever. The occurrence of allergic conditions in the families of these patients was frequent enough to indicate that hereditary factors are important. Whether there is a unit character that makes sensitization possible or impossible seems doubtful, but at least one can say that many of these patients come of a stock which shows an unusual tendency to become sensitized. In determining whether foods are responsible and, if so, what foods, skin

tests are of value, and intradermal tests seem more helpful than percutaneous tests. Elimination diets as devised by Rowe are the most useful means for the clinical determination of sensitivity to food. Symptomatic treatment, though often helpful, has been avoided as far as possible in this series in order to observe more accurately the influence of diet. In cases in which eczema is due solely to sensitization to a few unimportant foods their exclusion is the only treatment required, but for patients sensitive to one or more basic foods desensitization seems the only solution. The most practical method is that of Schofield and Schloss, by which there is a daily feeding of gradually increased amounts beginning with minute doses. Attempts to desensitize patients by ingestion of the "specific propeptan tablets" have been disappointing. The occurrence in these patients of other allergic symptoms, such as gastrointestinal reactions, urticaria, asthma, hay fever and migraine, indicates that the eczema is only one manifestation of the familial type of allergy. As this dermatosis is an expression of the familial type of allergy, a convenient designation for it is allergic eczema.

- Loss of Weight During Muscular Work**.—Hovland recorded the loss of weight during relaxation and during the performance of finger oscillation following the ingestion of large and small meals. Ten subjects were used four days each. Efficiency, judged by the increment of loss of weight during work as compared to the loss during relaxation, appears better after a light lunch, the advantage being greatest in the earlier part of the afternoon, immediately after eating. Maximal inefficiency, from the standpoint of the expenditure of energy, is found in the late afternoon, about four hours after eating.
- Quantitative Determination of Urinary Estrogenic Substance**.—The Smiths conducted a series of comparative analyses which demonstrated that chloroform, olive oil, ethyl

acetate and benzene could not be counted on to give complete recovery or quantitatively comparable percentages of estrogenic substance as it occurs in untreated pregnancy urines. Chloroform gave the lowest and benzene the highest values. Recovery experiments, employing twenty-four hour continuous extraction with benzene, revealed that assays on untreated pregnancy urines could not be used as a gauge of the amount of estrogenic material actually present, since in some cases more was recovered than had been demonstrable in the unextracted specimens. Pregnancy urines, after being boiled for from five to ten minutes with 15 per cent of their volume of concentrated hydrochloric acid, increased greatly in their estrogenic content. There was, however, no constant ratio between the amount found in the untreated specimens and the amount "freed" by acid treatment. The ratios varied between 1.15 and 1.40. When the concentration of acid and the time of boiling were varied, no greater increase in potency could be produced by changing the technic within certain limits and no destruction of "freed" hormone resulted from boiling for ten minutes with 15 per cent acid. This procedure therefore, was adopted and the estrogenic substance so recovered was called "total." In assays on the pure hydroxyketone, theelin, it appeared that on long standing in the slightly alkaline solution in which it is put up, theelin was bound, since when first diluted for injection the potency was considerably less than could be demonstrated after the diluted solution had stood for ten days or more. Acid treatment did not result in any further increase in its estrogenic activity. Acid treatment simply "freed" the theelin that was originally present. No relation between the p_r of urine specimens and the amount of free estrogenic substance could be established, but it seems probable that the amount of the material "free" at any one time in any one specimen depends on variations in the other urinary constituents. From repeated analyses over a period of one month on the fresh, slightly acid urines of a pregnant woman the values for "free" estrogenic substance were strikingly inconsistent from day to day, but the "total" estrogenic substance followed a uniform curve, rising steadily as the pregnancy advanced. The actual ratios of "free" to "total" substance varied between 1.5 and 0.30. The results on single specimens from twelve nonpregnant subjects showed ratios of "free" to "total" material varying from 1.1 to 1.35 +.

Roentgenologic Diagnosis of Tumors in Sellar Region

—In reviewing twenty-four cases of tumor in or near the sella, twelve intrasellar lesions and twelve suprasellar lesions, Nichols discusses the roentgenologic criteria observed in roentgenograms

of the sellar region and in encephalograms made following the injection of air. The signs on the roentgenogram indicative of pathologic changes in or near the sella include decalcification and erosion of the clinoid processes, calcification, and elevation or depression of either the roof or the floor of the sella. When these definite roentgenographic signs are absent, encephalography is employed. This method is most valuable in the case of a suprasellar tumor that may be visualized directly or may be producing a deformity of the ventricles or of the basilar cisterns. Encephalography is seldom necessary in making a diagnosis of intrasellar tumor, which usually produces sufficient calcification or deformity to make possible the diagnosis from the roentgenogram.

Air Shadow Normally Produced by Choroid Plexus—Dyke and his associates point out that during puncture of the ventricles in the posterior parietal region for the introduction of air, as ordinarily done, the brain cannula may accidentally come into contact with and traumatize the glomus of the choroid plexus or a vessel in the wall of the ventricle. This may produce a hematoma or edema of the choroid plexus or the ventricular wall, which can be recognized on the roentgenogram as a defect in the outline of the lower wall of the lateral ventricle situated in or near the position of the glomus. In the authors' cases the location of the abnormally large defect corresponded to the glomus of the choroid plexus. The defect occurred only after ventriculography and was on the side of the ventricular puncture when a single puncture was done. At subsequent encephalography the defect was definitely decreased in size. The disease from which the patient was suffering was in each case unrelated to the defect in the ventricle. A defect of large size was never observed in the routine examination of the roentgenograms taken in 1,400 cases in which air was injected only by the lumbar route. A hematoma in the ventricle near the position of the glomus following ventricular puncture was demonstrable in a case at postmortem examination.

Diabetes Mellitus and Pulmonary Tuberculosis—Since there is no general agreement regarding the management of diabetes complicated by tuberculosis and the effect of the pulmonary process on the carbohydrate metabolism, McKean and Myers discuss thirty-two of eighty cases selected for nutritional study. Each patient in this group was under observation in the hospital for six or more consecutive months, the average length of stay being 555 days. All seldom or never refused any

portion of the meals served to them and none, the authors believe, obtained additional food elsewhere. The group included five persons in the third decade of life, six in the fourth, ten in the fifth, eight in the sixth and three in the seventh. The sex distribution was about equal. The tuberculosis in twenty-seven cases was far advanced on admission and in five it was moderately advanced. April 1, 1934, seven of the group were dead, one was untraced and twenty-four were known to be alive. Nine of the latter cases were classed as arrested or apparently arrested, four as quiescent, four as improved and seven as unimproved. The deaths were all due to tuberculosis. None of the patients who died in the hospital showed a clinical degree of acidosis at death. Severe insulin reactions occurred in many whose strength was slightly or moderately impaired without threatening life. The available dextrose in the diet in excess of the insulin required to keep the blood sugar below 140, calculated on the basis that 2 Gm of dextrose is covered by 1 unit of insulin, may serve as an index of carbohydrate tolerance. The carbohydrate tolerance was regarded as markedly improved when there was an increase of more than 50 Gm in the available dextrose uncovered by insulin, slightly improved when there was an increase of from 15 to 49 Gm, and unchanged when there was an increase or decrease of less than 15 Gm. A decrease of from 15 to 49 Gm was considered a slight fall in carbohydrate tolerance, a decrease of more than 50 Gm a marked fall. According to these criteria, the carbohydrate tolerance showed a marked improvement during the period of hospitalization in eleven cases, a slight improvement in four, no change in seven, a slight fall in four, and a marked fall in six. Twelve patients had been under observation in diabetic clinics prior to the onset of the tuberculosis. Five of these showed a marked fall in tolerance with the advent of the tuberculosis, five a slight fall and two no appreciable change. Several patients showed periods of improvement and retrogression in the tuberculosis. It does not necessarily follow, of course, that the change in tuberculosis was responsible for the change in carbohydrate tolerance merely because the two were coincidental. However, care was taken to eliminate from consideration any period in which there was an obvious cause for the change in tolerance apart from the tuberculosis. In twenty-seven instances there was a parallel change in the tuberculosis and diabetes, in seventeen cases the two showed improvement concurrently, and in ten cases both became worse. In thirteen instances the courses of the tuberculosis and diabetes were divergent. An improvement in tuberculosis was accompanied by a fall in carbohydrate tolerance in six cases, whereas the reverse occurred in seven. There appears to be no fixed rule governing the effect of tuberculosis on coexistent diabetes. The courses of the two diseases are usually parallel but may be divergent. An intercurrent pleural effusion, however, is generally accompanied by a temporary fall in tolerance. A marked fall in tolerance occurred coincidentally with the development of an effusion in three cases, a slight fall in six, no appreciable change in three and a slight rise in one.

The Shock Syndrome.—Moon attempts to correlate the contradictory phases of the shock syndrome, pointing out that it results whenever the volume of blood inadequately fills the vascular system. This may result from loss of blood or fluid, or from atony or dilatation of the vascular walls, especially the capillaries and venules. Combinations of these two factors are the rule. Circulatory failure of this type results not from cardiac or vasomotor inefficiency but from an inadequate return of venous blood from systemic areas. Increased concentration of the blood is a constant feature of shock. This is of clinical value both in recognizing the condition and in determining its degree. Shock produces characteristic changes demonstrable by postmortem examination. These consist of marked capillary and venous congestion of the viscera, edema of lungs and mucosae, petechial hemorrhages in serous and mucous surfaces, and effusion of fluid into serous cavities. Not only does shock occur following extensive surgery or trauma, it is seen in a wide variety of clinical conditions including extensive burns, poisoning with various substances, metabolic intoxications, abdominal emergencies and severe acute infections. Cerebral hemorrhage and other lesions of the central nervous system may terminate in shock the mechanism of which is not evident. Perhaps prolonged vasomotor disturbance results in tissue

asphyxia, which in turn causes capillary atony and permeability. Shock develops in varying degrees. Maximal degrees lead to death by circulatory failure. Lesser degrees may be followed by recovery or by death from pneumonia. Many cases of secondary pneumonia have their origin in this type of circulatory disturbance.

Atopic Annoyances in Course of Pulmonary Tuberculosis.—Phillips uses the word "atopic" to characterize spontaneous acquired sensitization to a foreign protein, excluding the delayed inflammatory reaction of the infected individual to tuberculo-protein, a reaction generally described as "allergic." A series of 250 consecutive tuberculous patients are included in the study, fifty of whom showed during the period of observation clinically evident sensitization to identified foreign proteins. Four others had symptoms quite as typical, but their atopens could be demonstrated only by the therapeutic test. In thirty-four cases, sensitization to pollens was indicated by skin tests confirmed by the effect of pollen therapy and in certain instances further substantiated by the relief afforded by residence in the filtered air of an allergen free room. Sixteen patients were found to be sensitive to foods alone, and seven of the pollen sensitive group reacted to foods as well. The offending foods were most often those which the patients had taken in excess in the hope of gaining weight: milk and egg, cocoa, tomato, cod liver oil, wheat, potato and chicken. The four patients whose atopens could be identified only indirectly had eosinophilia, a positive family history and negative skin tests. The symptoms of food sensitivity resembled frequently the digestive disturbances incident to the toxemia of tuberculosis, less often, those caused by organic disease of the digestive tract. Both sorts were relieved by exclusion of the offending foods from the diet. The discomfort incident to pollinosis interfered with the patients' rest and was detrimental to their general health. Food sensitivity, in addition to this, impaired their nutritional state. In dealing with food sensitivity in tuberculous patients, the diet should not be restricted to the point of causing continued loss of weight. Patients with chronic tuberculosis on the rest treatment, spending most of their days and nights in the open air, are heavily exposed to pollen in the pollinating seasons. The same patients, leading a monotonous life and desiring to gain weight, are likely to eat in excess foods, such as milk and egg, and tend to become sensitized to them. Appropriate pollen therapy, before or during the attack, may safely be employed in the presence of active tuberculosis. The recognition and proper management of sensitivity to foreign proteins constitute a useful addition to the hygienic treatment of tuberculosis.

Reflex Contraction of Muscles of Middle Ear as Indicator of Hearing.—The experiments of Kobrak and his associates in determining the value of the reflex of the muscles of the middle ear as an indicator of hearing reveal that 1. The acoustic contractions of the tensor muscle are almost always present in rabbits and allow easy quantitative measurements under the same procedure as a clinical test with the audiometer. Quantitative comparison of the contractions in different animals does not always show satisfactory uniformity. 2. Continued observations on one animal over several hours show a remarkable constancy. The reflex is therefore reliable.

as an indicator of hearing for acute experiments 3 Continued observations on one animal over several days show a high degree of constancy 4 Comparison of the response of the left and that of the right tensor muscle does not show any considerable variation 5 Small changes of the position of the animal and especially of the position of the pinna do not produce considerable differences, so it is not important to place too much significance on minute displacements of the loud speaker or of the animal The application of the sound may be carried out in the natural way and not necessarily by means of rubber tubes 6 The comparison between the readings of two different but equally trained observers shows a constancy which is about equal to that in clinical tests of hearing Besides the experiments in rabbits, observations on the stapedius reflex in man have been carried out It was possible to compare the curve of hearing and the curve of the reflex response of the stapedius muscle quantitatively and to express the difference in decibels The inconstancy in the distance between the two curves is probably due to individual peculiarities of the middle ear (adhesions of tendon) However, the relationship between the two curves is such that a good curve of the reflex of the stapedius muscle may be taken to indicate a relatively good curve of hearing This might be used clinically, for example, in cases of malingering

Skin Test for Diagnosis of Gonococcal Infections—Corbus performed experiments that show that the specific exotoxin present in the gonococcus bouillon filtrate (Corbus-Ferry), when 0.15 cc. is injected intradermally, is in sufficient quantities to obscure the true allergic reaction in individuals infected with the gonococcus Clark Ferry and Steele pointed out that a large proportion of normal persons give cutaneous reactions when injected with dilutions as low as 1:1500 This precludes its use as a specific diagnostic skin test for gonococcal infections With this added information in mind the bouillon (Corbus-Ferry) filtrate was detoxified by fractional heating and experiments were performed, 0.1 cc. instead of 0.15 cc. being used It appears that in individuals with either negative or positive histories of gonorrheal infection a positive allergic

reaction with detoxified gonococcus filtrate (Corbus-Ferry) is evidence of gonorrheal infection It also appears that this allergic condition may be passively transferred to a normal person even as early as forty-eight hours after the onset of the infection It is likely that this allergic condition remains constant for the duration of the infection It is also possible that this skin test will have further value in determining when a given patient is cured of the infection

Incisional Hernias—Heineck points out that by eliminating the etiologic factors of incisional hernias the incidence of the deformity and infirmity can be minimized and almost completely prevented Every case of incisional hernia calls for fascial fortifying of the path of escape of the hernial contents The use of autogenous living fascia lata transplants, either as approximating sutures or as a substitute for hernial defects, has proved satisfactory when employed with proper technique A permanent bond of union and closure of the hernia results The use of the Masson "fascial stripper" facilitates the removal of autogenous living transplants and causes negligible and only minimal scarring of the thigh This instrument is made to glide between the muscles and the subcutaneous fat, detaching the fascia and cutting it in desired lengths Ox fascia lata, sterilized and preserved in alcoholic solution, can be used either as suture material or in sheets in the repair of postoperative hernial defects The use of ox fascia eliminates the objectionable feature of an associated operation on the thigh It has given satisfactory results

Studies on Relation of Bacterium Granulosis to Trachoma—The attempts of Tang and Chou to isolate Bacterium granulosis in 179 cases of classic trachoma were negative The specimens used for cultivation consisted of lacrimal secretions epithelial scrapings, follicular contents and tarsal conjunctival tissue The mediums used were "leptospira" semisolid medium and carbohydrate blood agar plates Attempts to induce trachoma in rhesus monkeys and in man by subconjunctival injection

tion of cultures of *Bacterium granulosis* were negative. A disease of the conjunctiva characterized by follicle formation, but with no pannus formation or papillary hypertrophy, was induced in two out of nine monkeys injected with human trachomatous material. *Bacterium granulosis* was not isolated at any time from either of these animals. Antibodies against *Bacterium granulosis* could not be demonstrated in the serums of twenty-six subjects suffering from acute or chronic trachoma.

Experimental Brucellosis—Feldman and his associates introduced two strains of *Brucella abortus*, obtained from swine and bovine sources, respectively, into a series of eleven adult mongrel dogs to determine (1) whether a definite state of disease could be induced and (2) whether there was any significant difference in the pathogenic behavior of the swine and bovine varieties of *Brucella* in dogs. Five of the dogs received the bacteria in suspension intravenously and six were fasted twenty-four hours and were fed the organism mixed with raw meat. *Brucella* agglutinins developed as early as the fourth day in animals receiving the organisms intravenously, and in this group titers of from 1:800 to 1:1,600 were not uncommon one week after the introduction of the organism. Successive titers varied considerably in many cases. For those animals receiving the infective agent orally, the agglutinative response was much slower and was never as pronounced as for those receiving it intravenously. In a few cases it was possible to isolate *Brucella abortus* from the blood stream, but only within two or three weeks after introduction of the infective material. From two of the dogs it was possible to obtain the organism in the urine. Although most of the dogs lived for several months after receiving the infective bacteria, clinical symptoms of disease and specific lesions of minor significance were observed in only one dog. From only two of the dogs did the authors succeed in recovering *Brucella abortus* after death, and both had received the infecting inoculum intravenously, one dog thirty-nine days and the other 185 days previously. There was no discernible difference in the pathogenic propensities of the two varieties of *Brucella abortus* used. While the dog is capable of producing *Brucella* agglutinins following experimental introduction of either the swine or bovine varieties of *Brucella abortus*, a profound resistance to the organism exists, which precludes in most instances the development of clinical symptoms and specific lesions.

Symptoms in Meningitis and Brain Abscess—Weinstein describes tuberculous meningitis in a man, aged 55, who was brought to the hospital in a condition of stupor. The consulting neurologist regarded the condition as a reactive or serous meningitis and as a focal cerebritis in the left hemisphere from an adjacent ear condition. Necropsy revealed tuberculous meningitis with no trace of any abscess cavity in the brain. The author in evaluating the symptoms of meningitis and brain abscess points out that the finding of a quiescent chronic otitis media reinforced by such symptoms as headache, motor aphasia, rigidity of the neck, increased reflexes and mental confusion prejudged and confirmed the diagnosis of otitic abscess. But all these manifestations of generalized intracranial pressure and to some extent focal localization may also be due to an infectious encephalitis. An otitic brain abscess must

originate by contact infection with a diseased temporal bone. Once the infection has crossed the meninges into the brain substance and induced an abscess, its growth is gradual. During this latent stage a number of vague toxic symptoms may appear. When the abscess becomes manifest, symptoms of toxemia become aggravated, signs of intracranial pressure due to its increase in size, and injury to vital centers, impairing or destroying their function, make their appearance. A quite constant and important pressure symptom is a slow pulse, below 50, while in meningitis it is usually rapid. Aphasic disturbances are among the first and most frequent dysfunctions as the result of destruction of brain tissue in the temporal lobe and the adjacent brain tissue, their existence points clearly to an abscess in that region. Rigidity of the neck is present in brain abscess, but mostly when it affects the posterior fossa, otherwise it is a symptom of associated meningitis just as the Kernig and the motor irritation symptoms, such as increased reflexes, Babinski and Oppenheim. Repeated lumbar punctures before and after a mastoidectomy performed on the author's patient gave a clear fluid, while every brain abscess should show a turbid liquor. The cerebrospinal fluid gave a sterile, clear, predominantly polymorphonuclear liquor with diminished chlorides. He concludes that these laboratory observations in conjunction with the several contradictory symptoms made the diagnosis of brain abscess, regardless of the alluring discovery of a focus of infection, if not improbable, at least questionable.

Lysozyme—Hilding states that there is a natural antiseptic, chemically an enzyme, that is found widespread through the body fluids and tissues. It has the power of destroying and dissolving certain groups of bacteria even when highly diluted. It is found most abundantly in tears, very abundantly also in nasal mucus. Its purpose in these two secretions seems to be to protect one from the atmospheric bacteria for which it is deadly. The pathogenic bacteria are inhibited in their growth by it but are not necessarily destroyed. The lysozyme content of tears falls moderately in a number of the acute external diseases. In fact, it falls during any epiphora. That this has any etiologic significance is not thoroughly established. In vitamin A deficiency and xerophthalmia, however, there is a marked decrease in lytic power that seems fairly definitely to have an etiologic importance in the development of infection and keratomalacia. The three humors within the eye showed little or no lytic power when tested and therefore probably contain little or no lysozyme.

Mumps Meningo-Encephalitis—Birnberg observed nine cases of mumps meningo-encephalitis in the last eighteen months. This relatively high incidence suggested the possibility that many cases may be unrecognized, further, the increase also of cases of epidemic encephalitis, during this period, suggests some possible causal relationship. The problem of diagnosis rests essentially on the knowledge that neurologic complications do occur and on the recognition of the related mumps, the circumstantial evidence of mumps contact or a

prevalent mumps epidemic To the author the relatively mild symptoms in comparison with the high spinal fluid cell count is a valuable differential criterion In treatment, spinal drainage and symptomatic procedures are all that are indicated

Recent Trends in Obstetric Analgesia—Based on the statements of seventy-eight of the leading obstetricians of the country, Hunt observed that 1 There is a great increase in scientific interest in the subject of obstetric analgesia on the part of the profession. 2 Numerous drugs in various combinations are being used in an attempt to meet the requirements under various conditions. 3 The ideal obstetric analgesia has not yet been perfected. 4 No routine method can be used in all cases, and there is no method that does not possess dangers for the mother and child unless handled with great care and intelligence. 5 The best results are obtained by being familiar with more than one method and individualizing the patient. Only large experience with various drugs will prepare the obstetrician to administer them skilfully. 6 The use of any method entails a greater expenditure of time and greater responsibility on the part of the obstetrician. 7 There is a distinct tendency away from a complete twilight sleep as well as a complete Gwathmey technic. Twilight sleep should be employed in well equipped hospitals by those skilled in its use. The Gwathmey method is adaptable for use in homes by practitioners. 8 There seems to be an increase in the use of scopolamine combined with various methods to increase amnesia. 9 Parts of various methods are being combined. 10 There is a great increase in the use of various barbiturates and a decrease in the use of morphine and its derivatives. Barbiturates can be given earlier in labor than any other drug, with less effect on the baby. 11 The most widely used and most satisfactory barbiturate in obstetrics is pentobarbital sodium. Its combination with rectal ether-oil after the method of Irving and others enhances its action and counteracts its tendency to cause excitability. 12 Rectal ether-oil is being used extensively in combination with the barbiturates and other drugs. 13 Serious attempts are being made to find a drug that will combine the favorable features of the barbiturates and yet be free from their tendency to cause excitement.

*Hypertension Simulating Thyrotoxicosis R. L. Hamilton and A. P. Knight Sayre—p 717

Hypertension Simulating Thyrotoxicosis—Hamilton and Knight believe that all patients suspected of hyperthyroidism should be examined carefully as to cardiac competence and blood pressure. A patient with an increased basal metabolic rate in whom there is also an increase in blood pressure should be critically considered as to whether the hypertension is due to the thyrotoxicosis or whether it is a separate or distinct entity. The symptoms of thyrotoxicosis and hypertension seem to be an expression of an increased tonus of the sympathetic nervous system, principally giving rise to an abnormal rhythm in the thyroid and adrenals. These symptoms are modified, however, by a mild parasymphaticotonia in certain cases. A study of 215 selected case records showed that there was an increase in the systolic pressure both in the exophthalmic group and in those patients with adenomas and hyperthyroidism, as compared to the control series. Patients with thyrotoxicosis followed by thyroidectomy showed a small drop in systolic but a slight rise in diastolic pressure. There is no noticeable relationship between the blood pressure and the basal metabolic rate, except in the general averages of some groups and then not to a significant degree. The changes in blood pressure were consequent on age. There was a definite increase in the blood pressure of patients with thyrotoxicosis compared to the control group. Hypertension was a relatively frequent occurrence in patients with thyrotoxicosis. There was a significant drop in the basal metabolic rates of all thyrotoxic patients following thyroidectomy, and the basal metabolic rate following thyroidectomy was practically the same as that of the control group. A review of the literature and a survey of the cases suggest that the adrenal and thyroid are intimately associated in the production of the symptoms of hypertension and hyperthyroidism and that the adrenals are apparently the dominant controlling factor. Therefore any treatment that might be directed toward the lessening of the adrenal activities should be of some value in the control of these diseases.

Benign Lymphocytic Choriomeningitis—Armstrong and Dickens describe a symptom complex of headache, fever, meningeal irritation, and cerebrospinal fluid under increased pressure, with an increase in cells (with a lymphocytic response dominant) above 50, coupled with a normal chloride, sugar and urea content in the cerebrospinal fluid and a negative spinal fluid Wassermann reaction. This disease entity has previously

been designated in man as acute aseptic meningitis. The virus of Armstrong produces a similar symptom complex in monkeys. The blood serum of patients who have recovered from the disease protects animals from the virus of Armstrong. This disease occurs sporadically in man and has been transferred experimentally to animals. Traub has isolated a virus from white mice, and Rivers and Scott have isolated a virus from human patients, which are serologically identical with the National Institute of Health strains of the Armstrong virus. This condition by priority should be designated acute aseptic meningitis, but "acute lymphocytic choriomeningitis" is a more accurate designation.

Perforation of Peptic Ulcers—Blalock performed experiments to find the factors which are mainly responsible for the rapidly developing signs and symptoms that follow the perforation of peptic ulcers. The alterations in the circulation which are produced by the introduction into the peritoneal cavity of the various juices of the upper intestine were studied. Bile, pancreatic juice, gastric juice and duodenal secretion were obtained by cannulation. The juices were injected with a syringe and needle into the peritoneal cavities of other dogs. 1. Following the injection of rather large amounts of one or more of the juices of the upper intestine the animals became ill almost immediately. There was usually an increase in the pulse rate and vomiting. 2. Death did not occur in any of the nine experiments in which sterile pancreatic juice varying in amounts from 11 to 39 cc per kilogram of body weight was injected. Infected pancreatic juice in smaller quantities produced death. 3. Bile that is recovered after the first several days following the cannulation of the common duct exerts more ill effects when injected into the peritoneal cavity than that which is collected later. Six experiments were performed in which uninfected bile obtained from animals operated on less than four days previously was injected into other animals in amounts equaling 21 cc. or less per kilogram of body weight. All the recipients became quite ill, but only one died. 4. Eleven experiments were performed in which equal quantities of uninfected bile and pancreatic juice were injected into the peritoneal cavity. The amounts introduced were closely comparable to those injected in the studies in which bile or pancreatic juice alone was used. Four of the animals died, and

it seemed quite definite that the combination of bile and pancreatic juice is more toxic than an equal volume of either of them. 5. Death did not occur in any of the nine experiments in which a corresponding quantity of gastric juice was used or in the three experiments in which duodenal secretion was injected. These two secretions seemed to result in less harm than a corresponding quantity of bile alone or a combination of bile and pancreatic juice. 6. The animals that died as a result of the introduction of one or more of the secretions exhibited marked reddening of the intraperitoneal structures. This reddening and the presence of massive fat necrosis was particularly marked in the experiments in which the mixture of bile and pancreatic juice was injected. There was usually a large quantity of free fluid in the peritoneal cavity at necropsy, but this quantity by itself alone was not sufficient to account for the decline in blood volume and death. It is possible that this quantity with the blood that was present in the many dilated intraperitoneal blood vessels might be sufficient. The increase in the concentration of the red blood cells in some experiments was extreme, while in others it was not marked. 7. Studies on the cardiac output and blood pressure were performed before and following the injection of bile or pancreatic juice or both. The major early alteration consisted of a decline in the blood pressure, as is found in primary shock, and the subsequent change consisted of a greater drop in the cardiac output than in the blood pressure, as is found in secondary shock.

Quantitative Determinations of Anterior Pituitary-like Principle and Estrogenic Substance in Pregnancy—The further quantitative studies of the Smiths of anterior pituitary-like principle and estrogenic substance in twenty-seven additional cases confirm their previous observations of excessive gonad-stimulating hormone and, less consistently, subnormal levels of the estrogenic in the toxemias of late pregnancy and eclampsia. They also indicate that 1. In normal pregnancy a peak in the level of anterior pituitary-like principle occurs during the second, third or fourth month, followed by a marked drop. During the remainder of pregnancy the anterior pituitary-like principle maintains almost a constant level. 2. The amount of estrogenic material increases as pregnancy advances, reaching a peak at term. There is usually a marked elevation of the substance level between the third and fifth months. 3. In cases of toxemia of late pregnancy, an excess of anterior pituitary-like principle has probably been present for some time before the appearance of toxic symptoms. High levels of anterior pituitary-like principle during the sixth and seventh months in apparently normal women, therefore, may indicate that toxemia will develop, whereas normal figures at this time favor the prediction of continued normal pregnancy. A rise after the seventh month may not be significant, since delivery occurs so soon. 4. No abnormal figures for anterior pituitary-like principle or estrogenic substance can be described as typical of miscarriage. 5. The nausea of early pregnancy may be associated with a low estrogenic factor. 6. Although the highest values for serum of the anterior pituitary-like principle have been encountered in cases of eclampsia, the degree of excess of anterior pituitary-like principle does not always run parallel with the severity of the symptoms. 7. Quantitative analyses of serum of the anterior pituitary-like principle may be of diagnostic assistance in differentiating between toxic and nephritic conditions. 8. Quantitative analyses on women who in the middle third of pregnancy are showing some toxic symptoms may be of prognostic value.

Chondrosarcoma—Roberg presents nine cases of chondromyxomatous tumors from a clinical standpoint. Six of these were malignant sarcomas, two chondromas and one a circumscribed chondrosarcoma occurring in a toe. The close histologic relationship of these tumors is reason for seeking a connection between their clinical course and deviations from a unity of structure and factors apart from their histologic composition. From these features are derived factors of prognostic value. 1. Limitation by a capsule of cortical bone, characteristic of the chondromyxomatous tumors of the small bones of the hand and foot, is usually accompanied by a slow, local

ized growth 2 A predominantly myxomatous tissue is less invasive and more slowly growing than that in which a greater differentiation of cartilage cells has occurred Although the standpoint that myxomatous tissue is the least differentiated form of cartilage seems confirmed in these cases, the implied contradiction may be explained by an inhibitory effect of the myxomatous matrix on the cells which are contained in it, and by the view that bony differentiation depends partly on the matrix supplied for its formation by the destruction of bone by the less differentiated cells 3 The chondromyxosarcomas arising on the basis of a preexisting osteochondroma or chondroma pursue a less rapid course after the assumption of a malignant character than those which are malignant from the outset 4 An incomplete operation greatly accelerates the growth of a chondrosarcoma 5 The more proximal location of this type of tumor in a limb, or the existence of such a tumor in bone simultaneously undergoing normal developmental metaplasia or in the neighborhood of numerous structures arising from precartilaginous connective tissue, makes the prognosis less favorable Resistance to radiation, the beneficial effect of which lies chiefly in the stimulation of reactive bone, makes this form of treatment useful only as a supplement to operation Local, complete removal of an isolated, circumscribed tumor, which exhibits histologically a comparatively uniform structure, makes possible a more radical procedure should there be recurrence For the undoubtedly sarcomatous members of this group, a resection or amputation is advocated, as much as possible should be removed of the adjoining tissues that are composed of cells which exhibit stages in early cartilaginous development related to the tumor itself, although of an orderly and normal architecture

Lymphedema of the Extremities—Ghormley and Overton review the methods of surgical treatment of severe forms of lymphedema and report the end results of cases in which treatment was given at the Mayo Clinic in the last ten years A sufficiently long interval has elapsed since operation to make it reasonably certain that final results have been obtained Sixty-four patients have been operated on by the modified Kondoleon method since Sistrunk's report of his technic in 1923 These cases have been followed over a period of from two to ten years The improvement among patients who were followed was graded on a basis of 0 to 4, the latter signifying almost complete relief According to this grading, the condition of 12.5 per cent of the patients was unimproved, that of 14 per cent was improved, grade 1, that of 7.8 per cent was improved, grade 2 that of 31.3 per cent was improved, grade 3, and that of 10.9 per cent was improved, grade 4 There was a mortality rate, both immediate and remote, of 9.3 per cent The three postoperative deaths made an operative mortality of 4.7 per cent Further analysis of the cases revealed that there was very slight relationship between the severity of the disease and the degree of improvement The results were influenced by the wearing of an elastic supporting stocking of some sort Some form of supporting bandage must be worn after operation Improvement was found in 72.5 per cent of those cases in which the patients were known to be wearing a bandage after operation, whereas the condition was improved in only 40 per cent of those cases in which a bandage was not worn The relative incidence of infection before and after operation showed marked improvement Of twenty-six cases in which the patients were suffering from recurrent attacks of infection of some sort, in only six was the infection worse or unchanged, whereas in nine it was much improved and in eleven it had completely disappeared

Celiac Disease Treated with Insulin and Dextrose—Schlesinger and Keele present a case of clinically typical severe celiac disease with rickets and symmetrical fractures Fat analysis of the stools was normal The cause of the disorder appeared to be bound up with a faulty carbohydrate metabolism Marked clinical improvement was obtained with insulin and dextrose therapy Progress was most clearly depicted by the increase in weight Despite a low fat diet, ultraviolet rays, calcium and viosterol, loss of weight continued steadily for eight weeks, amounting to 3 pounds 12 ounces (1,700 Gm) When insulin and dextrose therapy (insulin 3 units, dextrose 15 Gm. twice daily) was begun immediate improvement was noticed, with a gain of 4 pounds 12 ounces (2,155 Gm.) in seven weeks Two control periods are consistent with the fact that this gain in weight was due to the treatment The gain in weight was accompanied by general clinical improvement, and the whole mental outlook became brighter The stools were less frequent, firmer and no longer offensive Their total fat content remained normal At the same time the blood phosphorus rose to 64 mg per hundred cubic centimeters Estimation of the blood sugar no longer showed a flat curve but a more normal rise of 30 mg per hundred cubic centimeters The bearing of this and other similar cases in the literature on the etiology of the disease is discussed A tentative suggestion is made that a significant part is played by a disordered endocrine system

Gastromegaly from Arterioesenteric Compression of Duodenum—Miller and Gage discuss three cases of chronic duodenal ileus from arterioesenteric compression in new-born infants and submit the evidence on which the diagnosis is based The chief clinical features of the syndrome consist of the enlarged stomach (gastromegaly) causing protrusion of the upper abdomen and showing occasional visible peristalsis, and vomiting of the obstructive type, the vomitus being profuse, projected and containing mucus Alternatively, refusal of food may keep the vomiting in abeyance for the time being Roentgen examination will demonstrate the presence of obstruction in mild cases, and in the severe ones it will distinguish between complete and incomplete obstruction It easily excludes any form of pyloric obstruction and, especially in oblique views, may demonstrate duodenal stasis The opaque meal should be given directly after gastric lavage and should be considerably larger than the normal for the age to allow for the enlargement of the stomach Medical treatment, chiefly by means of gastric lavage, is capable of restoring the tone of the distended stomach, so that satisfactory progress is possible in spite of the persistence of some degree of duodenal obstruction It is urged that, when symptoms suggesting duodenal stenosis or atresia are found to arise from an incomplete duodenal obstruction, the possibility of duodenal ileus should be considered and a brief trial made of medical measures before submitting the infant to the extreme risk of an abdominal operation In exceptional cases, in which gross megaduodenum is present, operation is probably essential, but in the type described here there is no possibility of the performance of duodenojejunostomy

Early Anemia of Premature Infants—Mackay found in twelve premature infants a loss in the total solids of the blood in the second month of life, which reached its maximum in the third month with a parallel decrease in red cells and hemo-

globin. There was not, however, any alteration in the weight curves to indicate water retention. From Sanpaules's work presumably a loss of solid elements must be supposed rather than an increase of fluid in the third month of life, or else a change in the relative amount of water in the circulation and in the tissues. If there is a loss from the body of solid elements of the blood without change in the blood volume, the low blood cell counts would still indicate that the total number of corpuscles in circulation in the body is subnormal. No definite knowledge exists at the present time of the cause of edema in new-born babies, though excessive cooling of the body appears to predispose to this condition.

Effects of X-Rays as Determined by Blood Serum Tests—Scott and Hernaman-Johnson point out that the vanadic acid test carried out in apparently healthy people gives results of sufficient constancy to establish a norm. The vanadic acid sedimentation test is the outcome of the work of Bendien, Lowe and Coke. Ortho vanadic acid has the property of causing a precipitate in blood serum. Within certain limits, the amount of the precipitate is determined by the acidity of the vanadic solution that is added. When the vanadic acid test varies from the normal, variations in the "green field" appear to be a measure of resistance to disease, whereas the red field measures toxicity. Although the test is nonspecific, the graph affords a great deal of useful information when the disease is already known. When the test is positive in certain diseases, it can be brought back to normal by suitable wide field roentgen therapy. Examples have been given in cases of asthma, spondylitis and breast cancer. The use of the test is not limited to the control of roentgen therapy. In cancer, for instance, the favorable alteration in the graphs may be shown as a result of treatment of another kind, such as the injection of colloidal selenium. While the local effects of x-rays will always be of importance, the time has come when it should be realized that x-radiation is also a powerful drug, having a pharmacology and therapeutics of its own, which will repay the closest study.

Observations on Absorption of Carotene and Vitamin A—Drummond and his collaborators investigated the absorption of vitamin A and carotene administered to a patient suffering from a condition which led to part of the contents of the thoracic duct being diverted into the pleural cavities. Analysis of the fluid removed at intervals from the cavities of the chest enabled approximate estimations to be made of the amount of vitamin A and carotene absorbed by way of the chyle. It was found that a relatively small proportion of the carotene

administered orally could be accounted for by the pigment found in the chylous fluid, whereas in the case of vitamin A the amount recovered was such as to indicate an almost complete absorption. The vitamin administered as the free alcohol was found present in the lymph mainly in the esterified condition, and it is thought probable that the linkage with the fatty acids during passage through the intestinal walls accounts for the much higher coefficient of absorption as compared with that found when carotene was given. Observations on the chylous fluid show that over a range of reaction much wider than that encountered in body fluids no trace either of carotene or of vitamin A passed a dialyzing membrane. Both compounds appeared to be present in colloidal form and closely associated with the highly dispersed fat.

Tuberculin in Treatment of Cutaneous Tuberculosis—Burnell-Jones presents three cases of cutaneous tuberculosis treated with tuberculin. Each case is a law unto itself with regard to intervals between injections, increase and decrease of dose and the change of tuberculin, and clinical insight and experience have to be depended on. The arrest of disease and the improvement seen in these cases are strong indications that the work should be continued. In one of the earlier cases (not recorded) treatment was given for seven months before any change in the lesions could be seen. The author has heard a practitioner condemn tuberculin after using it in one case for only three months. All the cases treated were of long duration before tuberculin was given. One patient, notwithstanding the fact that allergy was marked, continued to improve with small doses. The author employs large doses only if the patient tolerates them without a rise of temperature or unpleasant general reaction. This tolerance varies. One patient will sometimes feel ill after 0.1 cc., whereas another will feel no discomfort after 16 cc. Increase of weight almost invariably accompanies the administration of tuberculin. Sooner or later one finds that the improvement is not as rapid as at first. Thus the author assumes to be a sign for temporary suspension of treatment or for extension of the interval in any case it behooves caution. It does not occur when any particular dose has been reached. Attention is called to the remarkable differences in the blood films one finds in the different types of cutaneous cases, and it is suggested that workers should do monthly differential blood counts in each case.

The Common Cold—Browning in his summary of the causation of the common cold states that 1 The common cold is, at least in some instances, due to an agent which is not habitually harbored by those attacked. This is proved by the outbreak of epidemics in isolated communities on the occasion of the first visit of strangers after an interval of no communication. 2 Evidence that an infective agent of the filter passing type is responsible is furnished by the transmission of colds to quarantined human subjects and chimpanzees by the intranasal instillation of sterile filtrates of the nasal secretions of persons in the early stage of colds. The causal agent can survive for a considerable period outside the body and is capable of proliferation in culture medium in vitro. 3 It is not determined whether the ordinary pathogenic bacteria which may occur in the upper respiratory tract are ever by themselves the causal agent of coryza, although there is no doubt that as superadded infections they are important in aggravating the condition and especially in bringing about complications. 4 The incidence of colds is to a great extent independent of climate but has some relation to weather. Thus a sudden fall in temperature tends to be followed by an outbreak, owing in all probability to a lowering of resistance of the tissues. Nothing is known regarding factors that may influence the virulence of the causal agents. 5 There is little or no evidence that the incidence of colds in a community is related to the general habits of living of its individual members.

Treatment of Postpartum Hemorrhage Due to Atony P Salacz—p 476
Note on Five Pelvis of Women of the Eleventh Dynasty in Egypt D E Derry—p 490

Puerperal Mortality and Morbidity—Thomson states that perineal lacerations account for 7 per cent of the morbid conditions. An open wound is fraught with danger of infection in any part of the body, but such a danger is markedly increased when the wound is in the neighborhood of the vagina or rectum. Delay in the repair of a perineal laceration allows the germs a sufficient time to gain entrance to the blood stream and, if the tissues are not sutured immediately, healing and repair do not necessarily occur. The toxemias of pregnancy render the tissues unhealthy. The untimely use of the forceps, which may result in laceration of the soft parts, hemorrhage and exhaustion after a prolonged labor, is provocative of puerperal sepsis and pyrexia. Vaginal intervention should be avoided as much as possible. In hospital work it is a great advantage to divide the clean from the suspect case. Patients suffering from pyelitis are often admitted to the hospital before their confinement in the same ward as the clean antepartum cases and it is certain that *Bacillus coli*, most often the cause of pyelitis in pregnancy, accounts for a percentage of the local and general serious infections of the puerperium. Other possible sources of infection are a baby with a discharge from the eyes, septic spots on its skin, nasal discharges and a septic umbilical cord. Babies included in these categories are not allowed to be fed by the breast until the evidences of sepsis disappear. If the clean cases were warded in one part of the hospital and the suspect cases were segregated and warded as doubtful and certain sources of infection, much of the puerperal sepsis in the hospital would disappear. The chief causative agent of puerperal sepsis, the streptococcus, may come from the patient herself. In the majority of cases the source of the infection is due to a discharge from the nose or throat of the attendant or patient when they cough or sneeze. Other sources are boils, abscesses, carriers of *Streptococcus haemolyticus* and the unnecessary routine vaginal examinations made during normal labor. A chronic infection of the pelvis, lighted up during labor and giving rise to acute symptoms, may lead to the death of the patient. Aerial disinfection is worthy of consideration. Puerperal antitoxin occupies a definite place among the preventive measures of puerperal sepsis. The use of acriflavine is limited to swabbing the skin round the vulva. Its use is satisfactory, especially when combined with ethereal soap 1 500. The administration of calcium sulphide in a group of 1,421 cases, including many complicated, gives a pyrexial rate (when cases febrile on admission are excluded) of approximately 3.5 per thousand, an irreducible minimum. Asepsis should be the routine practice, not antiseptics.

Epidemic Pemphigus of the New-Born.—Poole and Whittle aver that pemphigus of the new-born may occur either in endemic or in epidemic form, the latter variety has been

rare until comparatively recently but is now beginning to constitute a serious hospital problem. The disease may take various forms, the lesions being essentially vesicular. Its bacteriology, pathology, sources of infection, onset, course and symptoms, differential diagnosis and prognosis are discussed. The treatment falls into three phases: prevention, control of epidemics and treatment of cases. Prevention depends on infants not being handled by any one who is suffering from or in contact with an infective condition, and on scrupulous obstetric cleanliness and a rigorous nursing technic. In treatment of the actual cases the most satisfactory results are obtained by frequent cleansing with a mild antiseptic, followed by a dry dressing. Gregorson reports good results from repeated exposure to ultra-violet radiation, while Cole and Ruh think that the use of an autogenous vaccine is beneficial. Simpler measures are equally effective. In the Cambridge epidemic the cases were all isolated in a "septic ward", special nurses, who did not attend other cases, were responsible for the dressings, which were renewed every four hours by day and once during the night, if the dressings became soiled by excreta, they were changed at once. Whenever the skin was dressed, all unbroken blisters were pricked with a sterile needle. In all cases the babies' arms were splinted to prevent the spread of infection by scratching.

Induced Water Retention in Diagnosis of Epilepsy—Clegg and Thorpe repeated Jacobsen's procedure of differential diagnosis between idiopathic epilepsy and hysteria, administering large quantities of water by the mouth, accompanied by hypodermic injections of pitressin in sixteen adult epileptic subjects and seven nonepileptic controls. Their object has been to confirm his results, or otherwise, and further to see whether any changes in the osmotic pressure of the blood accompany the water retention. Pallor followed the administration of pitressin in each case, it usually became noticeable about five minutes after injection and lasted up to two hours. It was accompanied by slowing of the pulse, but there was no marked alteration in the blood pressure. After two or three injections the action of the drug on the intestinal muscle was shown by slight looseness of the stools. In all the cases the excretion of urine was diminished, and in one patient suffering from chronic nephritis considerable edema of the ankles and face was produced. Edema constitutes a definite contraindication to the carrying out of the test. There was a progressive increase in the body weight during the administration of pitressin and water, with a definite drop when it was discontinued. The excretion of urine was affected conversely. A fit occurred after the weight had increased by 4 pounds (18 Kg). Of the sixteen epileptic patients tested, twelve had one or more fits during the administration of pitressin in combination with water. In two of the four negative cases, the test had to be discontinued because of hiccup and vomiting. The other two were both cases in which the fits were normally infrequent. In none of the seven controls was a fit induced by pitressin and water, and in none of the epileptic subjects to whom water or pitressin was administered alone.

 *Santonin Test in Diagnosis of Hepatic Insufficiency F Fernandez —p 576

Santonin Test in Hepatic Insufficiency—Fernandez discusses the evaluation of the liver's detoxifying function. Santonin can be utilized to test the capacity of the liver to retain or eliminate foreign substances. It is insoluble in water and, administered by mouth, is dissolved in the intestine, rapidly absorbed, transported to the liver, where it is transformed into a similar substance (oxysantonin), and eliminated by the kidney. To test this process it was necessary to prepare standards. For this purpose 5 cc of a 1 per cent alcoholic solution of eosin was prepared, to which 5 cc. of distilled water was added. This constitutes the "mother solution." Six tubes, each containing 5 cc of distilled water, were placed on a rack. Twenty-five drops of the mother solution was added to the first tube, fifteen to the second and five to the third. Five drops of the mother solution was added to 5 cc of distilled water and fifty drops of the latter added to the fourth tube, ten to the fifth and three to the sixth. The fasting patient is given 0.03 Gm of santonin in a wafer and a glass of water. The patient urinates at this time and each hour for the succeeding eight or ten hours. Three cubic centimeters of each micturition is placed in a tube of the same caliber as that of the standards. Two cubic centimeters of lye of a 36 degree Beaumé density, diluted with an equal amount of distilled water, is added to each specimen. The yellow, slightly reddish color becomes readily visible. This is compared with the standards and the number noted. The patient should drink water frequently to increase the diuresis, since the concentration of the urine does not appear to influence the test. In normal persons the elimination of santonin begins at the end of one hour, increases progressively during three or four hours and then diminishes until the seventh or the eighth hour. When the test is compared in normal persons and various types of hepatic insufficiency, the curve is normal if the elimination of santonin is neither too early nor too late, too brief or too long, too high or too low. Intermittent elimination seems a definite proof of functional liver deficiency.

Contralateral Pneumothorax—Tobé and his collaborators have had their attention called to the favorable contralateral action in certain cases of pneumothorax. Their observations can be divided into three groups. In some instances in which the creation of a double pneumothorax was considered, the collapse of one lung was followed by a sufficiently satisfactory contralateral improvement so that the second pneumothorax was unnecessary. In some cases in which it was necessary to maintain a pneumothorax in extreme expansion, they noted an unexpected improvement of the contralateral lesions. Thirdly, in a case of spontaneous pneumothorax developing in the course of a serious bilateral form which seemed beyond the resources of collapse therapy, the contralateral lesions became improved in an un hoped for manner. The authors believe that a contralateral action can be sought in the presence of (1) bilateral lesions with a free pleura, (2) bilateral lesions when narrow adhesions make pneumothorax impracticable on the side of the most menacing lesions, and (3) lesions practically unilateral in which adhesions prevent homolateral pneumothorax. When these criteria are fulfilled and contralateral action is expected, the authors insist on the necessity of maintaining a negative pressure in the pneumothorax, the terminal expiratory pressure remaining definitely lower than the atmospheric.

Calcification of Gallbladder—Scopetta reports a case of complete calcification of the gallbladder in a woman, aged 62, who showed no biliary symptoms of either objective or subjective character. The patient was apparently in normal health, except for the presence of a laparocoele. The diagnosis of calcified gallbladder was made during the roentgen examination of the gastro-intestinal tract in connection with the presence of the laparocoele. A cholecystectomy was performed. The author believes that the diffuse calcification of the gallbladder that results in the formation of the "porcelain gallbladder" originates in an inflammatory process of long duration and spontaneous regression in the gallbladder. This hypothesis seems to be confirmed by the pathogenic mechanism of calcification of the pleura and the pericardium. The condition may follow an evolution without symptoms. The roentgen diagnosis of calcified gallbladder is an indication for cholecystectomy.

Sensitivity of Skin to Tuberculin—Cerviá and his collaborators say that the theories for the interpretation of the internal mechanism of the skin reaction to tuberculin are not unanimous. In twenty-nine patients suffering from pulmonary tuberculosis, the authors performed intradermal reactions with (1) physiologic solution of sodium chloride, (2) a nonspecific protein, (3) old tuberculin and (4) a mixture of old tuberculin and epinephrine. The authors conclude from a comparative study of the morphology of the papules and of the focal hematologic formula of the papules that a relation between the velocity of the reabsorption of the skin and the sensitivity to tuberculin cannot be proved. When the mixture of tuberculin epinephrine is used in the test, the sensitivity of the skin to tuberculin decreases and the reaction lasts longer than when tuberculin alone is used. The intradermal reaction to tuberculin is specific. There is a relation between the hematologic formula of the tuberculin papule and that of the peripheral blood. The focal lymphocytosis in the tuberculin papule is the manifestation of the condition of general allergy in tuberculous patients.

Tumor of Hypophyseal Infundibulum—Salus reports the history of a woman, aged 28, who became amenorrheal gained rapidly in weight (20 Kg), developed morbid sleepiness and complained of headache and vomiting. There was a lactating mammary gland. After about three months, visual distur

bances developed. The woman complained of a glittering sensation and of seeing fiery wheels. She also developed polydipsia. Tests revealed a tendency to retain water and sodium chloride. The basal metabolism was reduced (-40) and the specific dynamic protein action was absent. In the beginning of the clinical observation there existed multiple paracentral scotomas and later there was choked disk and hemianopia. The patient died several days after a surgical intervention. The necropsy disclosed a tumor the size of a walnut in the hypophyseal infundibulum. The tumor compressed the optical tracts and had destroyed the floor of the diencephalon. The hypophysis was enlarged, the anterior lobe showing diffuse hyperplasia. The adrenals were unusually large and rich in lipid, and the ovaries were atrophic. The author discusses the different symptoms, giving especial attention to the pathogenesis of the galactorrhea. He thinks that in this patient it was caused by hypophyseal changes. Then he points out that the concurrence of obesity and morbid sleepiness is a characteristic diencephalic syndrome and shows that recent studies have disclosed that the central regulation of the metabolism is localized in this area.

Nicotine Poisoning—Genkin and his associates made studies on fifty-five workers (forty-one men and fourteen women), who extracted nicotine and nicotine sulphate from tobacco leaves and some of whom developed symptoms of acute poisoning. The pathologic manifestations developing under the influence of repeated small doses of nicotine belong chiefly to the sphere of the vegetative nervous system. Many of the symptoms are manifestations of the irritation of the parasympathetic, such as bradycardia, arrhythmia, hyperacidity, spasms of the smooth muscles, excessive salivation, and sweating. Another group of symptoms indicates disturbances in the sympathetic. To this group belong vascular manifestations of an angiospastic character in the lower extremities, tremor and so on. General cerebral symptoms are the result of disturbances in the blood perfusion of the brain. Symptoms such as sleep disturbances, loss of memory and neurotic manifestations are caused by the direct toxic action of the nicotine on the central nervous system. The most frequent symptom and thus the one that is most important for the diagnosis of nicotine poisoning is bradycardia. It may appear also outside the acute intoxications. The authors think that it is not so much the result of a central action of the toxin as of the influence the toxin exerts on the nerve cells of the vagus (in the system of the intracardiac ganglions). The pupillary reactions likewise seem to have diagnostic significance. The authors observed in a considerable number of their patients either contraction of the pupils or a slowness of reaction.

Electrocardiographic Disturbances in Diphtheria.—Frank shows that, in addition to the polyneuritic, the cardiac disturbances predominate in so-called toxic diphtheria. The majority of fatalities that occur in this form of diphtheria are the result of cardiac and circulatory disturbances. The author analyzes the symptomatology of the children who died as the result of severe cardiac and circulatory disturbances. He reports nine cases of diphtheria in children who had severe disturbances of the cardiac conduction system and eight cases in which the electrocardiogram indicated severe impairment of the myocardium. The prognosis is unfavorable. The clinical aspects permit no definite evaluation of the extent of the impairment; the electrocardiogram provides a better insight into the severity of the disturbances. All the children in whom the cardiac conduction was greatly impaired died. The author rejects the theory ascribing early death in diphtheria primarily to the circulation, for he maintains that electrocardiographic changes are found quite frequently in the early fatalities, and he thinks that those patients in whom they were not demon-

strable did not live long enough. In this connection he points out that in cardiac infarct the electrocardiographic changes appear frequently from one to three days after the clinical event. However, the circulatory disturbances do play a part in the early fatalities. In the treatment of the circulatory disturbance and of the toxic impairment of the heart, he saw the best results following the combined application of epinephrine and strophanthin and of the various restoratives, but he admits that, once the myocardial impairment has developed, treatment is of little avail. He maintains that prophylaxis in the form of early serotherapy is the most effective treatment. The early administration of the serum is more important than the size of the dose.

Chronic Polyarthritides During Age of Growth—Schaefer asserts that the thought of a causal relationship between acute and chronic polyarthritides and the central nervous system is not entirely new, for it was discussed during the last century. It was given up during the bacteriologic era in spite of the fact that a causal agent could not be found. The author made observations on ten patients, all young persons, and describes the histories of four of these who had systemic disorders and in whom increasing stiffening of the joints and dwarfism, especially of the extremities, were the most noticeable symptoms. In some of these cases the central nervous system is involved. This is indicated by the mental disturbances and by the peculiar physiognomy. Many of the patients were mentally deficient, for there were retarded intellectual development and deficiencies in the emotional life. They were irritable, hypochondriac and melancholic. The severest mental disturbances did not always concur with the articular pains but frequently appeared also during the interval. The hypochondriac moods often appeared several weeks or even months before the articular disturbances. The peculiar masklike physiognomy of the patients resembles greatly that observed following epidemic encephalitis and during parkinsonism. This is a further proof that the brain is the site of origin of the disorder, the more so since deforming articular changes have been observed as sequels of epidemic encephalitis. The symmetry of the articular disturbances is another factor indicating the neurocentral origin of the disorder. The author shows that the patients presented a number of other disorders of central origin. He mentions scleroderma, excessive sweating and hypersecretion of the sebaceous glands. Moreover, the trophic disturbances in the muscles cannot be explained by the dysfunction of the joints, for they frequently precede the articular disturbances. The author thinks that the muscular atrophy is like the other symptoms of central origin. He concludes that the articular disturbances are not the primary factor but that the condition is a systemic disease the various symptoms of which are of central nervous origin.

- Cured Agranulocytosis During Nursing Age S. Wolff—p 357

Protein Deficient Fruit-Vegetable Diet in Diabetes—Fanconi reaches the conclusion that the protein deficient fruit-vegetable diet constitutes progress in the treatment of diabetes mellitus in children. If a diabetic child is brought to the hospital in a comatose or precomatose state or with a high acetone and sugar elimination, medication with stimulants, particularly caffeine, brandy and metrazol, is resorted to and fluid (alkaline mineral water) is given in large quantities. If the child is comatose, the fluid is administered subcutaneously or intravenously. After several hours, orange juice is given in increasing quantities up to 400 Gm each day. Depending on the age of the child, from 10 to 20 units of insulin is administered and the injection is repeated after two or four hour intervals until the comatose symptoms have disappeared or until the urine has become free from sugar. Then the child is given only fruit for from two to three days. Beginning with the fourth or fifth day, steamed and raw vegetables prepared with butter or oil are added and, after another two to four days, from one to two egg yolks, from 100 to 400 Gm of almond milk or from

30 to 100 Gm. of cream in coffee or tea are added. Later, from 10 to 50 Gm. of nuts may be added and eventually a small amount of bacon. Soon after that, from 30 to 100 Gm. of potatoes and from 20 to 50 Gm. of graham or whole grain bread may be added and, with that, the protein deficient fruit-vegetable diet is complete and may be continued for years. The daily minimum of carbohydrates is 100 Gm. If with such an amount the child is not free from glycosuria, insulin is given. Because of a perhaps unfounded fear of chronic protein hunger, the author gives his patients once or twice a week from 30 to 100 Gm. of calf's liver, fish or meat. However, this is done only after the blood and urine have become normal because, if given before this, the meat may cause a sudden increase in the sugar content of blood and urine. Exclusive fruit days are intercalated from time to time, when sugar and acetone reappear in the urine. The protein deficient fruit and vegetable diet rapidly increases the carbohydrate tolerance and soon makes the use of insulin superfluous. Moreover, the diabetic children like this diet better than the former strict diets.

The Injection of Salyrgan—Parade considers that excellent diuretic action of salyrgan has been established beyond a doubt. He thinks that more or less severe complications which may follow the administration of salyrgan are not sufficient reason to dispense with the preparation. However, he demands that this medicament be employed in cases of heart disease only if a suitable digitalis and strophanthin therapy, eventually together with diuretics, has not succeeded in counteracting the decompensation and the edemas. He says that several years ago he pointed out that the too sudden elimination of severe edemas in patients with certain types of heart disease may eventually produce severe cardiac disturbances. He reports a case in which threatening symptoms developed following the injection of salyrgan. The severe cardiac disturbances were recorded by the electrocardiograph. The patient apparently had an aortic and coronary sclerosis, which probably had produced degenerative changes before the attack. An injection of salyrgan, preceded by the treatment with small doses of strophanthin, was followed by a severe tachyarrhythmia accompanied by threatening general symptoms (vomiting, debility and collapse). It is probable that during the attack there developed disorders in the blood perfusion of the myocardium, for the temporary appearance of a "coronary" T wave (in lead 3) seems to indicate this. The author concludes that, in cases of coronary disease in which myodegenerative processes exist, extreme caution is necessary in the use of salyrgan. If its administration becomes absolutely necessary in such cases, a small trial dose (0.5 cc intramuscularly) should be given first.

"Methemoglobin Test" for Determination of Antianemic Action of Liver Extracts—Wilkinson and Deutsch call attention to the fact that, in order to replace the clinical test method for which uncomplicated cases of pernicious anemia during the stage of relapse are required, attempts have been made in recent years to devise laboratory tests for the determination of the efficacy of the antianemic action of liver preparations. So far these attempts have not been entirely successful. Duesberg and Koll devised a laboratory method consisting in the spectroscopic examination of the liver extracts after they have been mixed with hemolyzed erythrocytes and kept in the incubator (38 C) for one hour. The authors resorted to this method in the determination of the antianemic action of a number of extracts and compared the results of this method with the clinical tests. They found that there is no relationship between the hematopoietic activity revealed by the clinical test and the capacity to form methemoglobin disclosed by the spectroscopic examination. By careful heating it is possible

to destroy the antianemic liver substance, but the methemoglobin-forming principle remains almost unchanged. The antianemic principle of the liver is not identical with the methemoglobin-forming factor but occurs independently. Consequently the methemoglobin test of Duesberg and Koll does not indicate the presence or absence of the antianemic action capacity of liver extracts, and the clinical test remains as yet the only reliable method for the determination of the efficacy of an extract in pernicious anemia.

- Recording of Heart Sounds and Their Reproduction by Means of Phonographic Method G. Kayser and A. Weber—p. 1032

Motility Disturbances of Intestine—According to Gutzeit the orderly motility of the intestine is the resultant of a number of interdependent as well as of independent functions. In the case of the intestine, as in that of the heart, the mural nervous system insures an automatic motor activity that depends on its contents and its nutrition. The plurality of other influences on the motility is of a supplementary type and has the object of adapting the automatic motor activity to the changing requirements of the environment into which the organism is placed. To these influences belong all neurohumoral actions, congenital and independent, as well as acquired and conditioned reflexes, a number of promoting and restraining incretory factors, orderly ferment production that is adapted to the intestinal contents and, last but not least, the controlling action of the harmonic interrelation of the sympathetic and the parasympathetic and their dependence on superordinated cortical and subcortical psychic equilibria. As the harmonic collaboration of all these factors and their adaptation to changed requirements insure an optimal intestinal motility, a failure of the physiologic correlations produces disturbances. The author points out that disturbances in the intestinal motility may be absent in conditions such as typhoid and dysentery in which they ordinarily develop. He thinks that this cannot be explained by the location and the extent of the inflammatory process but that compensatory mechanisms are at work and that nutritional and climatic factors may play a part, but in addition to these environmental factors there are also some within the organism. He discusses disorders of intestinal motility in various disease conditions, such as hyperthyroidism, myxedema, parathyroid tetany, Simmonds' cachexia, Addison's disease, sprue and other conditions, and he mentions the motility disturbances that result when certain secretions (pancreatic, biliary and gastric) are absent, or in case of dyspepsia or gastro-enteritis. Finally he discusses constipation and its treatment. He emphasizes the necessity of careful stool and roentgen examinations and shows that the treatment with purgatives and with a diet containing great amounts of roughage may exacerbate rather than improve certain forms of constipation and produce colitis.

Behavior of Diastase in Blood in Gastritis—Voit and Pragal call attention to reports by other investigators, who found that an increase in the diastase content of the blood is not restricted to the diseases of the pancreas. On the contrary, by means of Ottenstein's procedure, which they consider more sensitive than Wohlgemuth's method, an increase in the diastase content of the blood could be detected also in other disorders. The authors decided to study the diastase content of the blood of patients with gastritis in whom there existed no clinical indications of an involvement of the pancreas. In some cases they employed the method of Wohlgemuth in addition to the Ottenstein method. They first determined in tests on normal persons that the normal diastase values vary between 120 and 200 mg per hundred cubic centimeters. Consequently they consider as pathologic only values that exceed 200 mg per hundred cubic centimeters. They further determined the

diastase content of the blood according to Ottenstein's method on forty three patients in whom the symptoms of gastritis predominated and found that the diastase values are increased in most cases. They think that this makes it probable that the pancreas is involved, although there are no other clinical symptoms on the part of the pancreas.

Microdetermination of Fat in Blood Serum—Kien and Wetzler-Ligeti investigated the fat metabolism in various skin diseases and in the course of these studies they developed a micromethod for the determination of the fat content of the serum. For the purpose of deproteinization and the extraction of fat, 2 or 1 cc of serum is added in drops to 8 cc. of an ether-alcohol mixture (three parts of alcohol and one part of ether) that has been placed in two centrifuge test tubes. Following a short boiling in the water bath, centrifugation is done and the clear fluid decanted into a test tube with glass stopper and evaporated. The sediment is washed three times more with the ether-alcohol mixture and each time the fluid is evaporated. After complete evaporation of the solutions a yellowish sediment remains, which contains the total amount of the fats that are extractable by the ether-alcohol method. This sediment is shaken for one minute with 2 cc of chloroform and after that for one minute with 10 cc. of purified petroleum benzin. Then it is left to stand for ten minutes. The mixture of chloroform and petroleum benzin is put into test tubes (of the type used for blood sugar determination according to Hagedorn-Jensen) and is well shaken and evaporated until only a few drops remain. These remaining drops are absorbed by strips of filter paper about 4 or 5 cm. in length and of a width slightly less than the diameter of the Hagedorn-Jensen test tubes. The strips are fastened to a linen thread and are carefully weighed. Four strips are required for every double determination. After the contents of the test tube have been absorbed by the strips of filter paper, the tube is washed twice more with from 5 to 7 cc. of purified petroleum benzin. Evaporation is done again and the last drops are again taken up by filter paper. The strips are dried in an incubator at a temperature of 45 C. until a constant weight has been reached, which is usually the case after about thirty minutes. The increase in weight indicates in milligrams the quantity of fat contained in the amount of serum that was examined. In order to determine whether this method really detects the total quantity of fat, control tests were made with carefully weighed quantities of triolein and tripalmitin. These control tests corroborated the reliability of the method. The authors found that the fat content of the normal serum fluctuates between 350 and 500 mg per hundred cubic centimeters. Greatly increased fat content was detected in uremia, diabetes and icterus. The authors emphasize that all containers used for this test should be cleansed with chromosulphuric acid.

Amino Acid Metabolism in Pregnancy J. Botella Lluis—p. 68

Relation Between Histology and Prognosis in Genital Carcinoma—Feldweg emphasizes that the mixed cancers (squamous cell carcinoma and adenocarcinoma combined) and the structureless cancers must not be disregarded in the histologic classification of cancers. He observed that the maturity

of the carcinomas increases with increasing age of the patient. He found that the results of the surgical treatment were slightly better in the less mature cancers. He noted considerable differences in the ray sensitivity of the various types of cancer. He found that the ray sensitivity of adenocarcinomas in the cervix and in the body of the uterus is less than that of squamous cell carcinomas. Fractional irradiation produces the best therapeutic results in cancers of average maturity, irrespective of where they are located and what degree of differentiation they present. The prospects of irradiation are best in cancers with a moderate number of mitoses and with a moderate degree of cornification. Severe inflammatory reaction in the connective tissue indicates a more favorable prognosis for irradiation or surgical treatment than does a milder reaction.

Pseudomyxoma of Peritoneum—Antoine describes seven cases. He maintains that the pseudomyxoma may originate in the appendix (the intestine) as well as in the ovary. Simultaneously existing pseudomyxomatous changes in ovary and appendix have developed side by side. The relatively frequent simultaneous involvement of the two organs is due to a tumor predisposition (atresia of the proximal portion) of the appendix. The jelly-like secretion is produced by the epithelium. The penetration of the jelly-like substance into the connective tissue is caused neither by the great pressure in the cyst spaces nor by a revision of the direction of the secretion from the cell but rather by a rarefaction of the connective tissue with compensatory filling of the spaces with the jelly-like substance. In discussing the treatment, the author states that the surgical treatment should be as radical as possible and should be followed by roentgen irradiation.

*So-Called Endotheliomas of Pleura. S. Scheidegger—p. 93

Cellular Allergy and Genesis of Cancer O. Reuterwall—p. 117

Relations Between Carcinoma and Tuberculosis in Human Subjects Gertrud Heddaeus—p. 140

So-Called Endotheliomas of Pleura—Scheidegger points out that epitheliomas of the lung are mentioned much more frequently in the older than in the contemporary literature. Following a review of the literature on pulmonary tumors, he describes four tumors of the pleura and lung. In three cases of primary tumors that had developed in the pleura, endothelioid formations and peculiar tailed cell forms were found in addition to true epithelial cell accumulations. In the fourth case, a true bronchial carcinoma, the same formations were found. In spite of their partially uncharacteristic structure, the pleural tumors cannot be traced to the surface cells. If tumors develop from the surface cells, they must be mesenchymal formations. However, so far the literature records no such observations. The author observed sarcoma-like formations in an immature primary peritoneal tumor and typical endotheliomatous formations in a multicentric primary tumor of the liver. In the latter case the development of tumor cells from the hepatic epithelium could be observed. All tumors described by the author must be regarded as immature and highly malignant. He advises that such terms as endothelioma, mesothelioma and perithelioma be avoided. He is of the opinion that the cancers of the pleura originate in displayed epithelial tissue buds. He wants the term epithelioma restricted to tumors that really originate in the vessels. Endotheliomatous formations and long-tailed cell forms are frequently found in pulmonary and pleural carcinomas.

Surgical Treatment of Nonresectable Duodenal Ulcer—Hollenbach shows that the surgical treatment of the non-resectable duodenal ulcer has been the subject of considerable

dispute in recent years, for neither gastro-enterostomy with closure of the pylorus nor Eiselsberg's exclusion has given satisfactory results. Consequently the duodenal ulcer the resection of which is impossible on account of its close relation to the pancreas or to the hepatoduodenal ligament can be treated by only two methods by simple gastro-enterostomy or by Finsterer's "resection for exclusion," designated also as palliative resection and consisting in large resection of the stomach with or without removal of the pylorus. The author discusses the attitude of several leading gastric surgeons, showing that in recent years resection for exclusion has been widely recommended but is still being rejected by some. He himself has performed it in seventy-five cases and in all but five cases has removed the pylorus. There were three fatalities among the seventy-five cases. In one case the fatality was caused by peritonitis resulting from duodenal insufficiency, in another by pulmonary embolism and in the third by a hemorrhage from the ulcer. A peptic ulcer developed in one case, but more than 90 per cent of the patients recovered completely. The author states that in the majority of cases the duodenum was severed on the upper edge of the ulcer and in some cases the resection was made right through the ulcer. He points out that the indurated tissues in the head of the pancreas are favorable for the suturing of the duodenum. By two rows of sutures through the thickened pancreatic covering and the anterior duodenal wall, duodenal closure can be done rapidly and without difficulty. In a case in which death resulted from an insufficiency of the duodenal stump, the author recognized the limits of this operative method. He thinks that in case of an ulcer which is far down and on the posterior wall and in which no induration has developed in the head of the pancreas it is difficult to perform the resection along the upper edge of the ulcer or through the ulcer because closing of the duodenum will be extremely difficult. In such cases it is advisable not to remove the pylorus.

Destruction of Syphilitic Virus in Conserved Blood—

The experiments reported by Oganessian and his collaborators were made in order to determine the behavior of the syphilitic virus in conserved blood and to find a method of destroying the virus without making the blood unsuitable for transfusion purposes. It was found that five days of storage in the refrigerator is sufficient to destroy the spirochetes in the conserved blood. The addition of quinine dihydrochloride in a concentration of 1:1,000 effects the destruction of the syphilitic virus in less than three days. If the conserved blood contains only a small number of spirochetes, the process of destruction is more rapid. The authors emphasize that the destruction of the syphilitic virus in the course of the storage of conserved blood does not justify neglect of the venerologic control of the donors. They merely wish to show that in case of transfusion of conserved blood there is less danger of the transmission of syphilis than if fresh blood is used for transfusion.

Insulin Therapy in Menorrhagia and Metrorrhagia—

Klawns states that the observation that menstruation is often postponed, when vaginal insulin treatment is employed for erosions or ulcerations, induced him to try insulin therapy in cases of polymenorrhea, that is, in patients in whom menstruation recurred every fourteen or sixteen days and persisted for from eight to fourteen days. He tried insulin therapy also in hypermenorrhea, in juvenile hemorrhagic metropathia, in preclimacteric metropathia and in hemorrhages resulting from myomas and disturbances of the adnexa. A later inspection of the literature disclosed that other investigators had observed a connection between the ovarian cycle and the action of insulin and that some had found a favorable action of insulin on menstrual disturbances. In menorrhagias and in metropathic hemorrhages the author's results with insulin therapy were not quite

as favorable as those reported by some other investigators. He thinks that the difference is due to the fact that he observed his patients for longer periods. However, he too observed a decrease in the duration and in the intensity of the hemorrhages in a considerable number of patients. In hemorrhages of inflammatory origin, other authors obtained more favorable results than did the author. However, his observations largely coincided with those of one other investigator in hemorrhages caused by myomas, polyps and anatomic changes in the uterine wall, such as chronic metritis, fibrosis of the uterus, and adhesive perimetritis, for in these cases insulin therapy had little effect. The author found cases of polymenorrhea well suited for insulin therapy, for the prophylactic administration of insulin prolonged the interval between the menstrual periods from fourteen to twenty-one, twenty-four and finally twenty-eight days. Moreover, the duration and the intensity of the menstrual bleeding were considerably reduced in a number of cases. To make the prophylactic administration of insulin effective, it was necessary to administer the insulin several days before the expected menstruation, when the insulin was given only during the last forty-eight hours, it proved ineffective. He discusses the action of insulin and describes animal experiments conducted to gain a better insight into this action mechanism. He concludes that the favorable results obtained with insulin therapy in the various forms of pathologic hemorrhages are the result of the improvement it produces in the metabolic processes, that is, better utilization of the carbohydrates, better glycogen fixation, more adequate water binding power of the cells and modification of the sympathetic nervous system, of the ovarian functions and probably also of the hypophysis. Correct selection of the cases, exact dosage and prolonged intermittent treatment are the fundamental requirements for the success of the insulin treatment. The simultaneous administration of ergotamine tartrate is contraindicated, as it increases the sensitivity to insulin.

*Myocardial Infarct. Review of Symptomatology and Diagnosis Based on Twenty Eight Observations. C. J. E. Holst—p. 221
Studies on Blood Sugar and Glycosuria in Exophthalmic Goiter. W. T. Andersen—p. 245

Myocardial Infarct—Holst states that many of the symptoms of myocardial infarct are so transitory that they can be confirmed only on examination at certain times and on repeated examinations. The rise of temperature is probably most often slight, but 39 C. (102.2 F.), possibly more, is frequent even in patients who recover, the duration of the fever is as a rule longer than commonly indicated, often from two to four weeks. Three types of leukocytosis with different pathogenesis may be seen. The sedimentation reaction is increased in practically all cases but is sometimes so slight and transient that it is demonstrated only on repeated examinations. The changes in the electrocardiogram consist of disturbances in rhythm observed also in other conditions, of paroxysmal ventricular tachycardia and, more nearly pathognomonic for myocardial infarct, of a shifting of the ST interval, a peculiar arc shaped configuration of the ST interval and transitory inversions of the T deflections. The frequent and often misleading occurrence of gastrointestinal symptoms is discussed. Two typical and two atypical cases are described.

PREVENTIVE MEDICINE

CHAIRMAN'S ADDRESS

R H RILEY, MD, DR.PH

Director Maryland State Department of Health
BALTIMORE

At the first meeting of the American Medical Association, held in Baltimore in 1848, a committee on public hygiene was appointed, with Dr James Wynne of Baltimore as chairman. At the second meeting of the Association, held in Boston on May 1, 1849 the first report of the committee was submitted. At a later date a section quite comparable to the present Section on Preventive and Industrial Medicine and Public Health was organized. The Council on Health and Public Instruction was established in 1910 and was succeeded in 1922 by the present Bureau of Health and Public Instruction. Through the publications of the Association, through the work of this section and the Bureau of Health and Public Instruction, through its broadcasting programs and other official agencies, the Association has provided helpful information to the public and encouraged the practice of preventive medicine and cooperative effort on the part of physicians with respect to all sound and reasonable measures for public health betterment.

Any open antagonism or passive resistance by the general practitioner to the practice of preventive medicine was declared by the late Dr William H Welch "to be a challenge to the health officials."

In Maryland we have always enjoyed the most cordial cooperation with the state medical society, the Medical and Chirurgical Faculty of Maryland, the Baltimore City Medical Society and the several county medical societies. All plans for public health activities are discussed by members of the state board of health with the council of the Medical and Chirurgical Faculty, and the final program has the support of the faculty. Most of the county societies have a public health committee, which meets with the county health officers to formulate the health program of the county.

I feel that any program approaching the ideal in preventive medicine must have the whole hearted support of the general practitioner.

It is stated that the position of the general medical practitioner is being steadily undermined by the modern development of public health clinics, hospitals and specialties. I cannot say how far this is true, but I do say that any loss in the position or influence of the general practitioner is good neither for the profession nor for the public. In our system of public health the general practitioner should be the keystone and a most

important factor in the whole program. The general practitioner, then, should be actively associated with the public health work of his community. The Maryland State Board of Health has always insisted that the physician should have a prominent part in the prevention and control of communicable diseases. Much progress has been made also in securing and holding the interest of a large part of the profession of this state in the maternity and child hygiene program.

EFFORTS IN MARYLAND

As an example of what the family physician may do in the control of communicable diseases, I cite Carroll County, Md, in which a very large proportion of the preschool and school population was immunized against diphtheria by the physicians, leaving to the full time health officer a small group which for some reason did not or could not get to the clinics held by the physicians. In the same county the health officer rarely is obliged to vaccinate children entering school as required by law. This is done entirely by physicians as a matter of course. Immunizations against diphtheria by physicians reached 1,237 in one small campaign recently conducted in that county.

In Washington County, Md the medical society appointed a public health committee, which cooperates with the county health officer in all matters relating to preventive medicine, child hygiene, maternal hygiene, venereal diseases, tuberculosis, and medical care of relief cases. The medical society took a very active part in a county-wide diphtheria immunization program recently. The encouraging feature was participation by all the members not only in the immunization but in the Schick testing that followed. Physicians were assigned to each school to do the Schick tests. All children showing a positive Schick test were referred to their family physicians for immunization. During the campaign, 5,179 children showing a preliminary positive Schick were immunized. Of this number, 1,839 were immunized by family physicians in their offices and 3,340 by the physicians and health officer at the schools.

In Prince Georges County, Md, the health department in the last year conducted preliminary Schick tests in all schools in the county. A total of 4,989 children were tested and all those who gave a positive Schick test were referred to their family physicians. The number of immunizations done by the physician is not yet available, however, some have reported that they have done quite a large number.

April 8, 1935, the Wicomico County Medical Society, on the eastern shore of Maryland, adopted resolutions as follows on participation in the public health program of that county:

"That the medical profession will assume joint responsibility with the health department and each

physician to immunize the children in his community or practice regardless of ability to pay

"That the health officer is to administer the program creating public opinion and response," by which is meant a program of publicity

At this meeting the medical society further agreed to cooperate with the health officer through the public health committee of the society in all matters pertaining to the program, and to take an active part in the antepartum clinics held at the hospital and in the various communities, and to cooperate in a plan for the lowering of the present high infant death rate of that county

Worcester County Medical Society about a year ago, on learning of the great prevalence of venereal diseases in the county, authorized the establishment of a clinic by the county health officer to which the members of the society would refer, for an examination and a Wassermann test, persons suspected of being infected. All persons receiving this service are to be reported back to the physicians sending them in. The physicians then will either treat these persons or will send them back to the clinic for treatment. Recently the same society, having learned of the high infant death rate that has obtained for years in the county, has asked the county health officer to provide antepartum clinics, which the neighborhood physicians will be privileged to attend.

In Montgomery County the county medical society and the health officer agreed on a plan for school examinations by the private practitioner. The physician will conduct the examinations, and the public health nurse will arrange the program, assist in the examinations and keep the records. No physician will examine the school children in his own district.

The Baltimore City Health Department is now in its fifth annual diphtheria prevention campaign, and the commissioner of health has said that the success of the diphtheria prevention campaign was due in a large measure to the active participation of the practicing physicians of Baltimore. The Baltimore City plan was to allow a period of four months to precede that portion of the campaign involving the city-wide publicity drive of May and June. During this preliminary period every effort was made by the health department to "skim off" into the offices of private physicians the cream of the diphtheria prevention practice. Figures are at hand for the campaign, which demonstrated, more than any earlier one, the growing interest and continuously increasing support of this public health project by the medical profession in Baltimore. The ratio of children under 5 years of age reported as inoculated against diphtheria in the offices of private physicians to those inoculated in clinics and dispensaries was 1 to 7 in 1933 as compared with 1 to 10 in 1932. The true ratio is probably more favorable to private medical practice, as reports from this source are as yet fragmentary. An effective and unusual permanent feature of the diphtheria prevention campaign was inaugurated Jan. 1, 1933, in the form of a six months personal greeting card from the commissioner of health, which since that date has gone daily in the mail to about thirty-five babies in Baltimore.

THE PROGRAM AGAINST COMMUNICABLE DISEASES

In the immunization program in a community the health officer might take as his objective the number of immunizations each year to approximate the birth rate of the preceding year.

"Today the battle for a clean environment and a minimum guaranty against destitution may be said to

be won." There can be found many who are equally positive regarding the accomplishments in the struggle against diphtheria, typhoid and smallpox.

Maternal mortality and the infant death rate for our country have responded in an encouraging manner to the preventive program, but much remains to be done. It will require the united efforts of those officially and unofficially engaged to hold the gains that have been made. The magnitude of the maternal and child health program in the United States may be judged by the number of live births reported in 1933, which was 2,064,944, or a rate of 16.4 per thousand of population. This does not include 76,837 stillbirths reported.

In the preventive program against communicable diseases, some notion will be gained of its size when I state that there are 11,500,000 children in the United States under 5 years of age who should be protected by vaccination and inoculations against those diseases for which specific agents exist. This list is rapidly increasing as new discoveries are made. In the school population alone there are 24,600,000 for the health of whom the medical profession should assume its share of the responsibility.

The value of these preventive measures is clearly demonstrated by the following figures, obtained from Surgeon General Hugh S. Cumming of the United States Public Health Service.

The death rate per hundred thousand of population for diphtheria for a group of states in 1930 was 4.6 and in 1934 had declined to 2.7. The United States Bureau of Census reports showing the death rates in the registration area in continental United States for a number of years reveal the low rate of 0.4 in one state, in 1933 several states had rates of less than 1. Diphtheria morbidity and mortality rates seem to offer a fairly sound test of the quality of medical service received by the community. The conquest of diphtheria is now in process. The methods of achieving victory are known. The date of complete triumph depends on the methods and intensity by which they are applied.

The rates for typhoid indicate that the efforts of the past and the constant vigilance of the present have had a most favorable effect on the downward trend of this disease. Typhoid has been brought under control and shows a continued decline. The death rate per hundred thousand of population for a group of states in 1930 was 3.7 and has shown a yearly decline. In 1934 it reached 2.3 and in a number of states it was even lower. If less diligence should be shown in the supervision of public water and milk supplies, inspections of general food supplies and control of the sporadic cases, the typhoid rate would show a marked increase.

Tuberculosis has responded remarkably well to the program for its control. Intensive studies of its epidemiology and more comprehensive methods for its control are now being conducted in many localities. The death rate per hundred thousand of population from all forms of tuberculosis was 68 in 1930 and has shown a decline reaching 54.3 in 1934. I may with some degree of pardonable pride call attention to the fact that it was in Maryland that the first concerted campaign for the control of tuberculosis had its origin. In 1899 Osler formed the Laënnec Society for the Study of Tuberculosis. Maryland had the first tuberculosis exhibit in this country and was the first state to register tuberculosis. It was in Baltimore that the first steps were taken preliminary to the organization of the National Tuberculosis Association.

DISEASES OF MIDDLE LIFE

The mortality of diseases of middle life remains high. The death rate per hundred thousand of population from cancer was 97.8 in 1930 and has continued to increase until in 1934 it was 107.9. Diabetes likewise shows an increase being 19.3 in 1930 and 22.9 in 1934. Diseases of the heart have shown a steady increase in death rates since 1930. The rate in 1930 was 210 and in 1934 it was 243.9.

Some time ago the American Medical Association prepared a manual for the conduct of periodic examinations. For some reason this movement has not spread as rapidly as its sponsors predicted. It is generally agreed that the heavy toll taken in middle life could be lessened if the plan of periodic examination and regular supervision by the family physician were generally adopted. In this way many diseases would be detected in their incipience and habits of living might be modified so that health might be conserved and lives prolonged for many years of usefulness and enjoyment.

MATERNAL AND INFANT MORTALITY

The maternal mortality rates show a slight decrease during the five year period 1930-1934. The rate in 1930 and 1931 was 6.2 and has shown a decrease each year, reaching 5.4 in 1934. Maternal mortality from puerperal sepsis has not fallen, despite the advances that have been made in the practice of medicine in general. A pronounced improvement in the prevention of puerperal sepsis can be accomplished if there is a close cooperation between public health authorities, the obstetrician and the general practitioner.

The total infant mortality given as deaths under 1 year per thousand live births was 62 in 1930 and shows a slight decrease reaching 56 in 1933 to increase in 1934 to 58. The infant mortality, except malformation and diseases of early infancy was 29 in 1930 and has fallen steadily each year to 25 in 1934.

INDUSTRIAL HYGIENE

Another important public health problem in which there is being manifested great interest at this time is industrial hygiene. Some health departments maintain separate bureaus or divisions of industrial hygiene and this branch of activity is assuming a more important role. This subject will be fully presented before the section. In dealing with industrial hygiene special methods are required. Nuisances can be extinguished or slums demolished as menaces to the health of the public, but these root and branch methods cannot be applied to the factory. It is not practicable to shut down an important process the moment it causes a hazard to the workers. One must, on the contrary, recognize the need to keep the wheels of industry turning and must take up the more difficult task of devising protection for the worker without arresting the work.

ADEQUATE ORGANIZATION

Under existing conditions of economic pressure the problems of public health become aggravated and the need of an efficient, well coordinated, clearly defined organization becomes correspondingly urgent.

A comparatively small percentage of the rural areas of the United States has the form of health organization that is generally recognized as adequate. At the close of 1933, 73 per cent of the rural population was without this form of organization. During that year fifty-five full time units were discontinued and only four established. Some of the losses of 1933 were

regained in 1934. I am glad to report that Maryland increased to 100 per cent the health service to the rural population during the latter year.

In closing, I wish to emphasize the necessity for whole hearted participation of the entire medical profession in the public health program if our people are to receive the benefits of existing knowledge for the prevention of unnecessary sickness and death.

CERTAIN MENSTRUAL DISTURBANCES

ASSOCIATED WITH LOW BASAL METABOLIC
RATES WITHOUT MYXEDEMA

SAMUEL F. HAINES, M.D.

AND

ROBERT D. MUSSEY, M.D.

ROCHESTER, MINN.

In 1933 we¹ reported the results of treatment, by the oral administration of desiccated thyroid glands, of twenty-seven patients who had amenorrhea or marked oligomenorrhea and low basal metabolic rates without evidence of myxedema. We found that, of twenty-two patients who had had periods of amenorrhea 59 per cent menstruated more normally after treatment than they had before. At this time we report the results of similar treatment of seventy-four patients who had amenorrhea, oligomenorrhea or menorrhagia and low basal metabolic rates. These patients were seen in the years 1929 to 1934 inclusive. The cases that were reported in the original paper are included in this study.

Since 1917 H. S. Plummer² has recognized a group of patients who had low basal metabolic rates without clinical evidences of myxedema. Litzenberg and Carey³ noted that menstrual disturbances which could not be accounted for by any pathologic condition in the pelvis were found with moderate frequency in such cases. Many of these patients also complain of fatigue states. There is at present no reason for assuming a pathologic basis for the low basal metabolic rate in these cases, signs of myxedema do not develop, however low the level of metabolism may be. The response of the basal metabolic rate to the oral administration of desiccated thyroid is not so consistent in these cases as it is in cases in which myxedema is present. Furthermore, the elevation of the basal metabolic rate is not followed by improvement as frequently in these cases as it is in cases in which myxedema is present. The presence of low basal metabolic rates among several members of a family and the finding of a low basal metabolic rate among great numbers of individuals who apparently are in normal health also argue against a pathologic basis for the condition.

Elevation of the basal metabolic rate in the group of cases under consideration was carried out by the daily oral administration of desiccated thyroid. During the first few weeks of treatment the patients were kept under close supervision, and frequent observations of the basal metabolic rate were made. When a provisional

From the Division of Medicine and the Section on Obstetrics and Gynecology the Mayo Clinic.

1. Mussey, R. D. and Haines, S. F. Amenorrhea and Oligomenorrhea Associated with Low Basal Metabolic Rates, *Am. J. Obst. & Gynec.* 27: 404-408 (March) 1934.

2. Plummer, H. S. Personal communication to the authors.
3. Litzenberg, J. C. and Carey, J. B. The Relation of Basal Metabolism to Gestation, *Am. J. Obst. & Gynec.* 17: 550-552 (April) 1929.

daily dose of desiccated thyroid had been decided on, some patients were allowed to return home for a few weeks or a few months, but in all cases subsequent observations and determinations of the basal metabolic rate were made. There is sufficient individual variation in the daily dose of desiccated thyroid to make it necessary to hold the basal metabolic rate at the optimal level for the individual patient. Therefore, patients were not treated unless they could be kept under observation long enough to work out the necessary dosage. Patients are seen from time to time in the course of improperly controlled administration of desiccated thyroid who show definite evidences of hyperthyroidism because of excessive doses, others are seen whose metabolism remains low because of inadequate dosage. We feel strongly that these unnecessary complications of this treatment should be avoided. This can be done only by careful observation and occasional determination of the basal metabolic rate for a few months, at least. In the group of cases under consideration the doses of desiccated thyroid varied from one-half to 3 grains (0.03 to 0.2 Gm.) daily. The original level of the basal metabolic rate was not necessarily a factor in determining the daily dose needed in any individual case. Because most patients feel best if the basal metabolic rate is held at about -3 to -8 per cent, this level was aimed at in the treatment. This metabolic level seemed as effective as higher levels in the treatment of menstrual disturbances and was much less likely to result in uncomfortable symptoms, such as palpitation, diminished heat tolerance, and weakness.

Because of the time necessary to establish properly the dosage of desiccated thyroid many patients found it impossible to remain under our care long enough to follow this method of treatment. We have not included in this report patients who received treatment elsewhere. Also, in many instances, the administration of other hormone preparations, the application of roentgen rays over the pituitary body and ovaries, or other treatments were used independently or in association with thyroid medication, cases in which these treatments have been employed have not been included in this report. No case in which the patient showed evidence of myxedema has been included in this report.

The specific factors that are included in this study can best be considered if the cases in which the patients had amenorrhea, oligomenorrhea or menorrhagia are divided into separate groups. The relationship of low basal metabolism to sterility and to repeated miscarriages is not considered in this report.

AMENORRHEA

Fifty patients who had had amenorrhea for varying periods were treated with desiccated thyroid. The average age of these patients was 26.9 years, the greatest number of patients (twenty-five) in any decade were between 21 and 30 years of age. Twenty-seven of the patients were married. After elevation of the basal metabolic rate, fourteen patients (28 per cent) reported no improvement in the menstrual disturbance, seven (14 per cent) reported slight to moderate improvement, and twenty-nine (58 per cent) reported that their menstrual periods were normal or nearly so. The average duration of amenorrhea in those cases in which the menstrual disturbances were improved was nine and one-half months. In eight of these cases the patients had had amenorrhea for one year or more, and of these one had not menstruated for two years, one for four years, and one for five years. The average duration of amenorrhea, in the cases in which the patients

reported that there was not any change in menstruation after treatment, was nine and two tenths months. One of these had not menstruated for two and a half years, and another had not menstruated for four years. Thirty-seven (74 per cent) of the patients in this group said that they were in better general health after the elevation of the basal metabolic rate than they had been before. Some patients who reported general improvement had not noted any improvement in the menstrual disturbance, and vice versa. The average basal metabolic rate in cases in which amenorrhea was relieved by the treatment was -18.1 per cent, that in the cases in which the amenorrhea was not improved by the treatment was -18.5 per cent. In each of these groups of cases the basal metabolic rates varied between -11 and -30 per cent.

OLIGOMENORRHEA

Nine patients who had varying degrees of oligomenorrhea were treated by elevating their basal metabolic rates. The average age of these patients was 30.6 years, six of them were married. Four patients (44.4 per cent) did not note any improvement in menstruation after the treatment, two patients (22.2 per cent) said that the menstrual periods were more normal than they had been, and three (33.3 per cent) said that their menstrual periods were normal or nearly so after the administration of thyroid. Six patients (66.7 per cent) noticed improvement in their general health after elevation of the basal metabolic rate. The average basal metabolic rate before treatment in those cases in which there was improvement in the menstrual disturbance was -19.8 per cent, and in those in which no improvement was noted it was -16.8 per cent.

MENORRHAGIA

Fifteen patients who were suffering from menorrhagia were treated with desiccated thyroid. The average age of these patients was 30 years, twelve were married. Four patients (26.6 per cent) did not note any change in the menstrual disturbance after elevation of the basal metabolic rate. In three cases (20 per cent) there was slight to moderate improvement of the menorrhagia, and in eight cases (53.3 per cent) the menstrual periods became normal or nearly so. Eighty per cent of the patients in this group noticed an improvement in general health after elevation of the basal metabolic rate. The average basal metabolic rate was -17.3 per cent in those cases in which there was improvement in the menstrual disturbance, and -22 per cent in cases in which the patients did not note any improvement in the menorrhagia. In another group of cases of menorrhagia, which is much larger than the present group, the patients were treated with curettage, with anterior pituitary or with other hormones, or with both curettage and such hormones, with or without desiccated thyroid. These cases are not included in this report.

COMMENT

The number of patients in either of these groups who would have noted improvement in the menstrual disturbances had they not had any treatments during the time they were under observation is, of course, unknown. Since the menstrual disturbances were of long standing in many cases, it seems evident that maintenance of the basal metabolic rate at or near the average normal level was a factor in the reestablishment of normal menses in at least a fair percentage of the cases. Fatigue states have been encountered frequently in these cases, as they have in many cases in which

there are low basal metabolic rates without evidence of myxedema. A high percentage of patients in each group noticed a diminution in fatigue after the basal metabolic rate had been raised. This experience has been widely noted in the entire group of cases in which there were low basal metabolic rates.

This method of treatment becomes of increasing interest in view of the opinion expressed in the past year by Frank, Goldberger and Spielman⁴ that the use of estrogenic substances appears entirely illusory, and because of the statement by Novak⁵ that anterior pituitary therapy is still largely a blank. We have not made any attempt to use the thyrotropic hormone of the anterior pituitary body in these cases, chiefly because of reports by Anderson and Collip⁶ and others of its temporary effect, and also because of the ease and accuracy with which elevation of the basal metabolic rate can be accomplished by the administration of desiccated thyroid. The work of Fluhmann⁷ indicates that thyroid substance inhibits the effect on the ovaries of the gonad stimulating hormone of the anterior pituitary body, and that this inhibition is the result of the direct effect on the ovary and not the result of indirect action through the anterior pituitary body. Although his observations seem to demonstrate that the thyroid gland has at least an indirect effect on ovarian activity, we are not prepared to say that this explains the results obtained following the administration of desiccated thyroid to patients who have menstrual disturbances associated with low basal metabolism.

SUMMARY

A group of patients who had amenorrhea, oligomenorrhea or menorrhagia and low basal metabolic rates were treated with carefully regulated oral doses of desiccated thyroid glands. Because of a desire to determine the effectiveness of desiccated thyroid alone in the treatment of these conditions no patients who received any other form of treatment are included in this report. Definite improvement in the menstrual flow was obtained in 72 per cent of the cases in which there was amenorrhea, in 55 per cent of the cases in which there was oligomenorrhea, and in 73 per cent of the cases in which there was menorrhagia. Aside from whether or not there was an improvement in the menstrual disturbance, about 75 per cent of the entire group of patients reported improvement in their general health after elevation of the basal metabolism to within the average normal limits.

ABSTRACT OF DISCUSSION

DR J. C. LITZENBERG, Minneapolis. The authors have brought out that there is a very definite relationship between the thyroid and the reproductive system and that there is a definite relationship between sterility and habitual abortions and the thyroid. The fixed idea that minus 10 to plus 10 is the normal basal metabolic rate leads to difficulty. That is true as to disease from the standpoint of the internist and the physician, but from a physiologic standpoint no one knows just what it is, because within these rates a great many cases have been treated with thyroid with favorable results in these functional disturbances. I wish to emphasize that in each individual the dosage must be established by the basal metabolic rate.

One-fourth grain (0.016 Gm.) of thyroid produced hyperthyroidism in a patient and, on the other hand, 5 grains (0.3 Gm.) a day failed to raise the rate, illustrating that each individual must be tested as to what her dosage should be. The results that I have observed are quite similar to those of the authors. One fourth of the patients with functional dysmenorrhea were improved when they had amenorrhea or oligomenorrhea and 60 per cent were definitely normal after the medication. The health of 80 per cent was definitely improved. Of course, speaking in percentages of small groups of cases probably does not express the exact condition of things. In 1926 I found that in sixty-nine cases of sterility the rate of the basal metabolism was low in 50 per cent and that with functional disturbances of menstruation, such as the authors have been discussing, 40 per cent of the patients were sterile. Out of 114 women, 40 per cent had functional disturbances. In 1929 our cases from the Nicolle Clinic were accumulated by my colleagues Carey and Blumstein. The number of cases by this time had been somewhat increased and the percentages have a little more value. There were 255 married women with low basal metabolic rates. Of these, 49.7 per cent were sterile, which agrees with our percentages of the smaller group. Of 469 with low basal metabolic rates 39.7 per cent had such disturbances and 63 per cent were improved. In all the different types of functional menstrual disturbances of approximately 500 women the improvement was 68.2 per cent.

DR T. J. WILLIAMS, University, Va. Many women with functional disorders of menstruation show essentially normal metabolic rates, although even in this group some improvement in the menstrual irregularity may follow thyroid medication. Excessive menstruation seems more likely to be associated with mild hypothyroid states than is scanty or absent menstruation, although in either instance irregularity of rhythm is common. The widespread use of some of the more recent glandular preparations without a complete examination and study of the patient has occasionally permitted lowered thyroid activity to be overlooked as a possible associated cause in menstrual disorders. I recall a young woman who at the age of 19 developed a functional amenorrhea and who for two years was treated with various glandular products. At this time, the basal rate was minus 22 and amenorrhea persisted. Under thyroid medication the rate was raised to minus 11, at which level menstruation recurred. On several attempts to discontinue the thyroid, amenorrhea recurred and the basal rate dropped as low as minus 40 on one occasion. In December 1933, after two years of thyroid therapy, it was finally discontinued and the periods remained regular in all respects until September 1934, when a pregnancy occurred, which has proceeded normally. In my hands the best results in the treatment of the functional menstrual disorders have been in individuals with lowered basal metabolism treated with thyroid. Definite improvement in from 55 to 73 per cent of the cases suggests that this method of therapy is simpler and more satisfactory than any of the other methods available at the present time. An important consideration in these individuals, aside from the correction of the menstrual disturbance, is the improvement in the general health and well being and the relief of fatigability and lassitude that are associated with the elevation of the basal rates. It is questionable whether the employment of the thyrotropic hormone of the anterior pituitary body, even if readily available, would have any great advantage over desiccated thyroid in the treatment of these patients. Patients treated with thyroid preparations should be under close observation, and, in deciding on thyroid therapy and in determining dosages, the physical signs of thyroid activity should be considered as well as basal metabolism determinations.

DR R. D. MUSSEY, Rochester, Minn. Dr. Litzenberg has called attention to the fact that percentages of small groups of cases sometimes are not absolutely accurate, I agree with this, yet I feel that these figures show the trend of results of treatment. This group is small because we have reported only cases in which we have exercised personal supervision during the course of the treatment. In addition to the low basal metabolic rate, it was realized that some of these patients may have had disturbances in the production of estrogenic or gonadotropic substances, and in some of these cases determinations of estro-

genic or gonadotropic substances or both were made. These determinations have not been carried on long enough to evaluate the possible association of any appreciable number of cases in which the basal metabolic rates were low and in which estrogenic and gonadotropic determinations may have also shown a variance. As a rule, thyroid treatment has to be continued for an indefinite period. We have noted that, when patients improve on thyroid medication, the discontinuance of this treatment is commonly followed by lowering of the metabolic rate and a relapse to their former condition.

CONGENITAL SYPHILIS

DIAGNOSIS BY MEANS OF DARK-FIELD EXAMINATION OF SCRAPINGS FROM THE UMBILICAL VEIN

NORMAN R. INGRAHAM JR., M.D.
PHILADELPHIA

When one is dealing with an infectious disease, demonstration of the causative agent is always desirable in order to establish the diagnosis. The necessity for demonstrating the organism varies inversely with the vividness of the clinical picture presented by the patient. A new-born syphilitic child is usually free of symptoms during the first few days or weeks of life.¹ Hence, the demonstration of *Spirochaeta pallida*, were this possible, would be a valuable diagnostic aid.

Obtaining material in which to demonstrate spirochetes from a living child suspected of having syphilis presents a problem which is often insurmountable. It is true that spirochetes have been shown to be present in the blood stream,² the nasal secretion,³ the conjunctival secretion,⁴ syphilitic cutaneous lesions, the urine^{2c} and in the meconium⁵ of syphilitic infants, but in most instances the infant in whom the causative micro-organism is found has manifest clinical evidence of congenital syphilis or has succumbed to the disease before birth or shortly afterward. Spirochetes have been revealed in certain instances in all the products of conception in the placenta, the umbilical cord, the amniotic fluid and the various fetal membranes, but so far as diagnosing syphilis in the new-born child is concerned the demonstration of histologic changes or of spirochetes in the placenta or in the fetal membranes, however valuable it may be for demonstrating

the presence of syphilis in the mother, will never indicate with certainty whether or not the child is diseased (McCord,⁶ McKelvey and Turner,⁷ Trinchese⁸). There remains for purposes of diagnosis the umbilical cord.

This structure is unique in that, while it forms an important part of the fetal circulation, it is readily accessible for laboratory study after birth and it is the avenue through which the spirochetes must pass from the mother to the child, if the latter is to become infected. Several modes of transfer of the spirochetes from the maternal to the fetal circulation have been suggested,⁹ but the theory of permeation of the lymphatic system mentioned by Rietschel¹⁰ is the one that is of most concern in this study and the one that will accordingly be described. In brief, a transient spirochetemia in the mother infects the maternal portion of the placenta. An inflammatory reaction in the smaller blood vessels results in a swelling of the media, in an obliterative endarteritis and in the formation of a small infarct. Spirochetes multiply rapidly in this area, permeate the tissue membrane separating the maternal and fetal circulation and gain access to the tissue spaces in the fetal portion of the placenta. The fluids from these areas drain into the lymphatic vessels which course, in part at least, in the perivascular tissue surrounding the umbilical vein and apparently in the wall of the vessel itself. Thus the spirochetes gain ready access to the fetal organism through these channels.

Spirochetes have been described as present in the umbilical cord by a number of European workers.¹¹ As early as 1906 Huebschmann¹² and Simmonds¹³ found spirochetes in sections of umbilical cord stained according to the Levaditi silver impregnation method. Other investigators confirmed their work.¹⁴ These pathologists, however, were interested primarily not in the diagnosis of the disease in the infant but in showing the manner in which the fetus is infected. Thomsen and Boas¹⁵ in 1909 did remark, none the less, that the demonstration of spirochetes in the umbilical cord was a difficult procedure and of little practical value from a diagnostic standpoint. lishing a year later in this country, came to a similar conclusion, having found spirochetes in silver stained sections of the umbilical vein in only one of fifteen syphilitic infants. More recently, Manouelian,¹⁷ in attempting to show the primary lesion of congenital syphilis, demonstrated the presence of many spirochetes in cases of periphlebitis of the umbilical vein. As a result of the combined investigations of the aforementioned workers, it has been learned that spirochetes may be found in the wall of the umbilical vein, in the wall of the umbilical arteries, more rarely in the blood within the lumen of these vessels, and in the jelly of Wharton, but it is agreed that the microorganisms are most numerous and most easily demonstrated in the wall of the umbilical vein.

Of more practical value, however, than the demonstration of spirochetes by histologic examination of silver impregnated microscopic sections, a procedure that requires a number of hours of work and an intimate knowledge of a rather specialized technic, is the demonstration of spirochetes by dark-field examination of fresh preparations made from scrapings from the wall of the umbilical vein. Gräfenberg¹⁴ mentioned having used this method as early as 1908, but it was rediscovered by Vulović¹⁸ in 1923 and since has been employed with more or less success by other investigators, especially Klasten¹⁹ and Philipp and Gornick.²⁰ They have considered the method of absolute diagnostic value in a limited number of cases. More than a year ago, McKelvey and Turner,⁷ reporting from Johns Hopkins University on syphilis in pregnant women, stated that they had attempted this diagnostic procedure but had found it too cumbersome for routine work. In view of the fact that the cord must be examined shortly after delivery, the method necessitates, in hospital practice, close cooperation between the medical and nursing staff and a full-time resident physician skilled in the use of the dark-field method.

One of the more important contributions in this field of study was that of Vulović, in Vienna, who examined 1,024 specimens of umbilical cords in unselected maternity cases and found spirochetes in seven. Two of the seven patients inadequately followed were never proved to have syphilis. Vulović subdivided the cases in which the dark-field examination gave negative results into the following groups: 703 apparently normal infants, 280 cases of supposedly nonsyphilitic abortion and stillbirth, seventeen apparently healthy infants of syphilitic mothers, fifteen macerated fetuses and two infants of mothers infected during pregnancy. Each of the mothers in the seven cases in which the dark-field examination was positive was proved to have syphilis.

Klasten in 1925, without stating the number of specimens that had been actually examined, reported twelve

instances in which spirochetes were found in scrapings from the umbilical vein. In all of these, with the exception of the case of one infant who was free of symptoms at the age of 11 months, syphilis developed. Klasten also found spirochetes in the cord of three of thirty macerated fetuses. Philipp and Gornick in 1926 reported positive results of dark-field examinations of material from the umbilical vein in nine living offspring and in fifteen still-born children of syphilitic mothers, all the living children being followed and the diagnosis of syphilis being made clinically. In the last nine years the method has been mentioned occasionally, but there are no reports of its having been used in any extended series of cases.

METHOD OF DARK-FIELD EXAMINATION

The method, as described by Vulović and as employed in the present investigation with slight modifications, is briefly as follows:

Immediately after delivery a portion of the umbilical cord, about 3 inches (7.6 cm.) long, is cut from the distal end (the end farther from the placenta and nearer the child). This is placed in a sterile moist bottle and kept without preservative at room temperature. For best results the examination must be made as soon as possible after the infant is born, for, if

8	2	Secondary	8 months	3	4+	4+	—

the specimen stands for much longer than eight hours before it is studied, bacterial contamination begins to become evident and the possibility of obtaining a positive result is greatly diminished. When the examination is performed, the ends of the specimen are cut off and discarded, the middle inch (2.5 cm.) being saved. The two arteries and the single vein are then identified in cross-section without too great difficulty. The vein is best transfixed by passing through it from end to end some small blunt instrument, e. g. a probe (toothpicks have been used for this purpose), and the lumen of the vein exposed longitudinally by cutting down on the probe with a sharp scalpel. The blood adhering to the intima of the vessel, which somewhat hinders the study by making the spirochetes more difficult to find, is scraped away with a knife. The knife is then wiped clean and additional scrapings are taken from the wall of the vessel, placed in a drop or two of physiologic solution of sodium chloride, macerated, placed on a slide and examined in the dark-field microscope.

Spirochetes are never numerous. I have found one preparation, from a stillborn fetus, in which there were approximately twelve micro-organisms per field, but usually many fields were examined before a single spirochete was found. A specimen was called positive when at least two actively motile micro-organisms, morphologically *Spirochaeta pallida*, were revealed, it was called negative after examination of at least two preparations, for not less than one-half hour, did not demonstrate the presence of spirochetes.

RESULTS OF STUDY

Dark-field examination was made of fresh preparations of scrapings from the umbilical vein in ninety-five unselected deliveries of syphilitic mothers at the Philadelphia General Hospital between May 31, 1934, and April 1, 1935. Spirochetes were found in twenty-five instances: six times in stillborn fetuses, nineteen times in living infants. None of the living children showed clinical symptoms at the time of delivery, and no treatment was given, but all the infants were followed sufficiently long to establish the diagnosis by some other means, clinically, serologically, roentgenographically.

From the practical standpoint it makes little difference whether or not spirochetes are demonstrated in the umbilical cord of a stillborn infant, since in those cases the damage has already been done to the child and the diagnosis of the disease is readily accomplished in the mother by means of blood tests. These cases are accordingly considered separately in table 1. The serology of the cord, which in this hospital is tested by means of the Wassermann reaction in two antigens and checked against the Kahn reaction, was invariably positive, the mothers had received little or no antepartum treatment, and spirochetes could be demonstrated in the scrapings from the umbilical vein in 75 per cent of cases.

It is with the living infants that the present study is principally concerned, for it is in such cases that treatment early and judiciously applied will decrease the infant morbidity and mortality resulting from congenital syphilis. The data concerning the nineteen liv-

ing infants who showed positive evidence under dark-field examination. The information obtained from the roentgenograms of the long bones, a much more valuable diagnostic aid for detecting congenital syphilis at the time of birth or shortly afterward, was compared with that from the umbilical vein in sixty-two instances (table 3). In nine instances the roentgenograms

showed definite positive evidence, whereas the examination of the umbilical vein showed negative results. Spirochetes were found in the umbilical cord, on the other hand, in twelve cases in which the child had not been infected long enough for the changes to become evident in the bones, and in which the diagnosis could not have been made in the first week of life by any other method. Eighteen (25.7 per cent) of the infants in whom the dark-field examination was negative were subsequently proved to have syphilis.

In case 10 (table 2) positive evidence of syphilis was obtained from an examination of the umbilical vein, but the infant has not been proved to have syphilis clinically by studies thus far made. This infant is the fourth child of a white woman with latent syphilis and with strongly positive blood serologic test, who received only two injections of neoarsphenamine prior to delivery and whose last child showed clinical evidence of syphilis with strongly positive serologic proof at the age of 7 months. At the age of 4 months the child had a generalized lymphadenopathic condition but was otherwise healthy. A blood test was negative and roentgenograms of the long bones at six days and at four months were negative. It is still possible that in the youngest child clinical symptoms of syphilis may develop. One infant, case 5, followed for nine months, has not shown a positive blood reaction, even though he has not received any treatment. He is the third child of a woman with latent syphilis and a strongly positive blood reaction, who received only one treatment prior to delivery and whose last antecedent pregnancy resulted in a late miscarriage. Roentgenograms of the long bones of the child at the age of 6 days and of 2 months showed typical osteochondritic changes. The infant, who at birth weighed 6 pounds 3½ ounces (2,820 Gm.) and weighed only 11 pounds (5 Kg.) at the age of 9 months, appeared pale and sick, with obvious obstruction to nasal breathing and an enlarged and palpable liver and spleen. A clinical diagnosis of syphilis was made by the pediatricians.

Although there is no reason to think that spirochetes or artefacts resembling them would be present in the

ing children in whom the specific micro-organism of syphilis was demonstrated in the scrapings from the umbilical vein are summarized in table 2.

The unreliability of the Wassermann reaction as an absolute diagnostic criterion in early infancy is well established and generally recognized.²¹ The Wassermann reaction of serum from the cord was positive in only three (16 per cent) of the nineteen living syphi-

circulation or tissue of nonsyphilitic infants careful dark-field examinations have been performed on preparations from the umbilical vein in fifty cases in which the infant was not suspected of having syphilis. These have proved to be negative in every instance to microscopic test and to subsequent clinical investigation.

It is perhaps worthy of note that spirochetes were demonstrated by dark-field examination in only two cases in which over two months of antepartum treatment had been given, twenty-three (92 per cent) of the positive results having been obtained in cases in which little or no treatment was given (table 4). The average duration of treatment in the group in which positive evidence was obtained was three weeks as compared to nine in the infants in whom the dark-field examination was negative. There is a noticeable tendency for the percentage of syphilitic children detected to decrease as the amount of antepartum treatment increases. It is probable, therefore, that the amount of treatment which the mother receives prior to delivery forms a definite restriction to this method of diagnosis. This method is of greatest value when delivery takes place at the height of the spirochetal invasion of the fetus.

SUMMARY

In this series of cases dark-field examination of the umbilical vein has been instrumental in detecting syphilis in nineteen (21.8 per cent) of the eighty-seven living offspring of syphilitic mothers on whom it was tried, with an accuracy which might be considered 100 per cent, and at a time in the infant's life when most other clinical criteria and laboratory aids are unsuccessful. Since thirty-five of the living infants studied, however, were actually proved by observation to have syphilis, it is needless to say that a negative dark-field examination does not rule out syphilis in the child but merely indicates the necessity of studying the infant by other methods. The fact that in 54 per cent of the diseased children the diagnosis was made within a few hours after birth seems to indicate that this method has a diagnostic value which somewhat overshadows its clumsiness. It is truly impractical to examine a specimen of the cord obtained at every delivery in a large maternity service, but, when the diagnosis of syphilis is made in the mother, as it should be, before delivery takes place, then the suspected syphilitic specimens can be examined without placing too great a burden on the physicians in charge, and the diagnosis of congenital syphilis can be established immediately in a limited number of cases.

THE DIAGNOSIS OF CONGENITAL SYPHILIS

A. H. PARMELEE, M.D.

OAK PARK, ILL.

AND

L. J. HALPERN, M.D.

CHICAGO

A large number of infants born of mothers known to be syphilitic show no clinical symptoms of the disease during the first weeks of life. Likewise a comparatively large number give negative serum reactions. Roentgenologic evidence of bone lesions characteristic of congenital syphilis is the only other known diagnostic sign of the disease. How reliable this sign is,

Chart 1—Graphic comparison of the relative value of the three diagnostic methods in cases in which records of examinations were complete. Straight line indicates roentgenologic, broken line clinical, dots and dashes serologic.

compared to the clinical and serologic evidences in the diagnosis, was the question we hoped to answer when we started the work on which this report is based.

We studied a series of infants born of mothers known to have syphilis by making periodic clinical, serologic and roentgenologic examinations during the first year of life.

Our material comprises 104 consecutive infants born at the Cook County Hospital during the two year period from the autumn of 1928 to the autumn of 1930. A careful physical examination was made during the

Chart 2—Probabilities for diagnosis of congenital syphilis at the various periods during the first year. Straight line indicates definite, dots and dashes, suggestive, broken line, total.

first few days of life, blood was drawn for Wassermann and Kahn tests, and roentgenograms were made of the long bones. The same procedure was followed at 6 weeks, at 3 months, at 6 months and at 1 year. Owing to various reasons, the records in some cases are not complete, therefore we have included in our comparative statistics only those cases with recorded observations on all three types of examinations.

Read before the Section on Pediatrics at the Eighty-Sixth Annual Session of the American Medical Association, Atlantic City, N. J., June 14, 1935.

From the departments of pediatrics of Rush Medical College of the University of Chicago and of the University of Illinois College of Medicine and from the Cook County Hospital, Chicago.

Under the heading "clinical" are included those signs and symptoms usually referred to as suggestive of congenital syphilis enlarged spleen, rhinitis, marked desquamation of the palms and soles, pustular or macular rashes, pseudoparalysis and the like. Since these symptoms can rarely be considered diagnostic without the support of other evidence, they are here designated "suggestive observations." Very few infants in this group had clinical manifestations sufficiently marked to warrant a diagnosis without support from other diagnostic aids. With this explanation it is evident that in the charts and table the importance of clinical symptoms is more apparent than it is real.

The accompanying table is a statistical summary of the study as it relates to the comparative diagnostic value of clinical, roentgenologic and serologic observations at the various periods studied. Chart 1 shows this comparison in graphic form.

These statistics show in a striking manner the predominant importance of the roentgenologic evidence of

conclusions as to the relation of these factors to the incidence of or the degree of severity of infection in the infant. However, 83.7 per cent of the infants studied in this series showed either definite or suggestive evidence of infection at some time during the first year. Sixty-seven cases, or 64.4 per cent, were considered positively infected. In 95 per cent of these sixty-seven positive cases a diagnosis could be made

Summary of Cases in Which Records of Examinations Were Complete

osseous syphilis in the diagnosis of congenital syphilis during early infancy. During the new-born period there was suggestive clinical evidence of infection in 19 per cent of the cases, serologic evidence in 23 per cent and roentgenologic evidence in 44 per cent, at 6 weeks the figures are 30 per cent, 8 per cent and 61 per cent, and at 3 months 25.7 per cent, 8.6 per cent and 63 per cent respectively.

Chart 2 is suggestive of the probabilities for the diagnosis of congenital syphilis during the first year of

Chart 3—Relative value of roentgenology and serology in the diagnosis of sixty-seven definitely infected infants during the first year

evidence of infection in the first year. The degree of fixation of the virus in the mother probably determines the occurrence of symptoms and signs in the offspring.

We were unable to get either satisfactory data concerning the time of the mother's infection or accurate enough information about her treatment to draw any

Chart 4—Relative incidence of osteochondritis alone, both osteochondritis and periostitis and periostitis alone in the various periods

through the evidence of osseous lesions as revealed by roentgenograms. Only 29 per cent of these sixty-seven cases gave positive serologic tests.

The changes that occurred in serum reactions deserve some attention. In seven infants the Kahn reaction was 1 plus and in four it was 2 plus, with a negative Wassermann reaction in the first period, they all had negative Kahn reactions in the second period. Three infants who had 2 plus Kahn and 2 plus Wassermann reactions and one who had a 4 plus Kahn and a 4 plus Wassermann reaction in the first period were Kahn negative and Wassermann negative in the second period. Of three infants whose serum reactions were negative in the first period, two gave 4 plus reactions in the second period and one in the fourth period. One infant with a 1 plus Kahn and a negative Wassermann reaction in the first period had a 4 plus Kahn and a 4 plus Wassermann reaction in the fourth period, and another with a 2 plus Kahn and 1 plus Wassermann reaction in the first period had a 4 plus Kahn and a 4 plus Wassermann reaction in the third period. These observations indicate that too much reliance on the serum reactions during the new-born period may lead to errors in diagnosis.

No attempt will be made in this report to discuss the bone changes in congenital syphilis, but in chart 4 we show graphically the relative incidence of osteochondritis occurring alone, of osteochondritis and periostitis occurring together, and of periostitis occurring alone in the various periods of the first year.

Periostitis is almost never present in the new-born. It becomes moderately frequent by the sixth week and is present in more than half of the cases showing osteochondritis by the third month. It is extremely rare for periostitis to occur as the only change in the bones of syphilitic infants.

COMMENT

The frequency of the occurrence of pathologic changes of the bone in congenital syphilis has been common knowledge among pathologists for many years.

As early as 1778 Nils Rosen¹ called attention to the frequency of bone lesions in congenital syphilis and emphasized the value of skeletal examination in these cases. In 1864 Ranvier² mentioned arrest of ossification as a paramount manifestation of congenital syphilis. The observations of Wegner³ were published in 1870 and those of Parrot⁴ in 1871-1873. Fränkel⁵ emphasized that bone lesions are most pathognomonic of congenital syphilis in 1873.

With the development of roentgenology it became possible to visualize the pathologic lesions in the osseous system. The first demonstration of roentgenograms of syphilitic lesions of the bones in congenital syphilis was made by Hochsinger⁶ in 1900. In 1907 Oluf Thomsen⁷ of Denmark pointed out that the roentgen ray offers the best method of discovering congenital syphilis in new-born infants otherwise showing no evidence of the disease. The German and French literature of the last twenty years contains much important information on this subject. Among the outstanding contributions are those of Eugen Frankel,⁸ Bela Alexander,⁹ Hans Wimberger,¹⁰ and M. Pehu¹¹. Thus the significance of bone lesions in congenital syphilis has been much stressed in Europe, but until Stafford McLean¹² published his thorough and exhaustive studies in 1931 the American literature contained very little on the subject.

Our purpose in this report is to call attention once more to the overwhelming significance of osseous lesions as revealed by the x-rays in the diagnosis of congenital syphilis.

715 Lake Street—1301 North Western Avenue.

ABSTRACT OF DISCUSSION

DR. JOSEPH YAMPOLSKY, Atlanta, Ga. With the intensive antepartum treatment of syphilitic mothers given in most of the clinics it is becoming apparent that the diagnosis of congenital syphilis will have to be made less on clinical signs and more through serologic and roentgenologic methods of examination. Between 50 and 60 per cent can be diagnosed at birth. Careful monthly serologic follow ups will probably by the fourth month determine all syphilitic cases, as it has been proved by other writers that, if the Wassermann reaction is negative after the fourth month, it is probable that an infant although born of a syphilitic mother probably does not have syphilis. It has been interesting to note that an infant whose spinal Wassermann reaction is positive and whose mother is definitely syphilitic is usually syphilitic in character. Some may not be syphilitic,

as has been proved by Dunham, who demonstrated that the Wassermann reaction in these cases becomes negative later. She states that this phenomenon is due to the fact that the complement fixing substance of the mother's blood is transmitted to the infant, in whom it remains for a few weeks and then disappears. In a study of 1,372 living babies by McCord, 114 per cent of full term babies later demonstrated a positive serologic reaction and 28 per cent of premature babies showed the same evidence. When no antepartum treatment was given, 221 per cent of the patients demonstrated a strongly positive reaction, as against 2 per cent in whom sufficient antepartum treatment had been administered. There is no doubt in my mind that the roentgenologic examination of the new-born is an efficient method for the determination of syphilis. In 309 dead infants, McCord demonstrated roentgenologically syphilitic bone changes in 623 per cent. It may be interesting to note that in the same patients the organism of syphilis was found in 61 per cent, demonstrating that the results of roentgenologic examination were favorably comparable with the finding of the organisms. In another study of seventeen cases treated with acetarsone at the ages of from a few months to 12 years it was possible to demonstrate roentgenologic changes in fourteen, and therefore I agree with the authors that roentgenologic examination is important in the diagnosis of early congenital syphilis and that the typical observations will be those of osteochondritis, or of osteochondritis and periostitis occurring together in early infancy, and of periostitis occurring alone in the various periods only after the first year of life. I do not wish to go into the diagnosis of the demonstration of congenital syphilis through the examination of the mother's placenta, as antisyphilitic treatment of pregnant women has a definite influence on the histologic appearance of the placenta. I doubt that correct diagnosis can be made in that manner.

DR. H. HARRIS PERLMAN, Philadelphia. Diagnosis of prenatal syphilis in the early stages has become decidedly more difficult within the past decade, because of the intensive campaign that is being waged with unrelenting seriousness in antepartum clinics. This serious drive has resulted in a scarcity of clinical material to a degree so marked that the Sigma Clinic of the Children's Hospital, with an average weekly attendance numbering eighty or more patients, has been handicapped in presenting to our postgraduate students infants and children demonstrating the classic signs of so-called congenital syphilis. Contrast this situation with that which prevailed only ten or fifteen years ago. From the academic point of view the problem in prenatal syphilis today is particularly one of early diagnosis. The roentgenogram has been invaluable in demonstrating indisputable signs of prenatal syphilis when evidence of this disease is lacking in the new-born, when a history of syphilitic infection in either parent and other members of the family is indefinite or of doubtful value, and when criteria for the diagnosis of prenatal syphilis in the infant yield presumptive evidence alone. A diagnosis of syphilis on purely roentgenologic evidence without serologic or other confirmation, however, must be considered of doubtful value unless the roentgenologic signs are interpreted by an expert. It is a matter of routine at the Sigma Clinic of the Children's Hospital to have roentgenograms of the skeletal system taken in all infants under 1 year of age. Needless to state, a positive diagnosis of prenatal syphilis is frequently made by roentgen examination alone when other diagnostic means, including the blood Wassermann and Kahn reactions are negative. Dennie emphasizes the importance of the roentgenologic examination of the long bones in the following words: "The roentgenologic view is diagnostic in that the worm eaten areas can be seen between the epiphysis and the diaphysis and often the capsular portion fits like a cork in the end of the shaft." It is generally believed that the bones are more likely to be involved in prenatal syphilis than in acquired syphilis. Usually several of the bones are involved. Epiphysitis shown as a marked rarefaction or destruction at the epiphysal line of the long bones is seen in from 70 to 90 per cent of cases of prenatal syphilis during the first three months of life. Periostitis is a later manifestation and is demonstrable as a thickening along the entire shaft of the bone. Findlay, in his series of cases, found an incidence of bone lesions of 25 per cent. Dennie, in a study of fifty cases, stated that 40 per

cent had no other syphilitic signs than the bone lesions. In a survey of thirty early cases of prenatal syphilis by Broomer, fourteen showed no evidence of any bone lesions, osteochondritis and periostitis were present in twelve, dactylitis in one and Parrot's node was discovered in one. In most instances the blood serologic examinations have paralleled the roentgenologic and clinical observations.

DR. A. H. PARMELEE, Oak Park, Ill. I was afraid that nobody would believe the figures that I gave today. In fact, I was astounded at them myself. I think that they show two things: first, that serologic tests are not reliable during the early months of the first year in the diagnosis of congenital syphilis, and second, that physicians must learn to make their own roentgenologic interpretations. I am convinced that, if these films had been sent to the roentgenologist for his interpretation alone, unless he was one who had had special training in the recognition of osteochondritis, perhaps half of them would have been returned as negative. My appeal is that every pediatrician should become familiar with the early evidences of syphilis as revealed by roentgenology. The worm eaten appearance is not an early manifestation. The earliest manifestation is the thickened epiphyseal line with a narrow zone of rarefaction immediately shaftward in the metaphysis. One does not find periostitis in the new-born. It is found after six or eight weeks or later. My purpose in this paper primarily is to show that in the general run of practice, when physicians examine children physically, send the blood specimen to a laboratory for Wassermann and Kahn tests and examine the roentgenologic films of the long bones, they will find a very small number that show physical signs of syphilis and a surprisingly small number that will give positive serologic evidence of syphilis, but, if physicians become familiar with the roentgenologic signs of syphilis, they will find a surprisingly large number that do show some evidence of syphilis.

JUVENILE DEMENTIA PARALYTICA

WITH SPECIAL REFERENCE TO ITS TREATMENT WITH MALARIA

UDO J. WILE, M.D.

AND

EUGENE A. HAND, M.D.

Professor of Dermatology and Syphilology and Instructor in Dermatology and Syphilology, respectively, University of Michigan Medical School

ANN ARBOR, MICH.

Up to 1917, when Wagner-Jauregg presented his remarkable results in the treatment of dementia paralytica with malaria, the prognosis was extremely poor. This new form of treatment was soon instituted by others, who corroborated his observations as the years went by. O'Leary and Welsh¹ reported similar results at the Mayo Foundation. One of us,² reporting the observations in this clinic, found similar results.

The prognosis in juvenile dementia paralytica has been considered more unsatisfactory than in dementia paralytica. Almost as soon as malaria and other forms of fever therapy were used in adult dementia paralytica, it was tried in the juvenile type. O'Leary and Welsh¹ reported little if any improvement. Though the consensus is that the prognosis in the juvenile type is almost as poor today as it was before 1917, very little has been written on the malaria treatment of this condition.

There were seen in this clinic 1,040 cases of congenital syphilis from Jan. 1, 1925, to March 1, 1932, of

which thirty-one cases were juvenile dementia paralytica. A presentation of these cases with special reference to a comparison of those treated with malaria and those treated without malaria will be presented in this paper.

OBSERVATIONS

Sex—For every case of adult dementia paralytica in the female, about seven are diagnosed in the male. The protective effect of sex and pregnancy being eliminated in juvenile dementia paralytica, it would be expected that a larger proportion of females would be diagnosed than was found in the case of adult dementia paralytica. Most other writers state that juvenile dementia paralytica is about equally divided between the sexes, however, in this series twenty-three, or 74.2 per cent, were males and eight, or 25.8 per cent, were females. It could possibly be deduced from this that the protective influence of sex, though a factor, is of less importance than is that of pregnancy.

Age of Onset—The youngest patient to be clinically diagnosed as having juvenile dementia paralytica was 2 years of age and the oldest was 31. In most of the patients symptoms developed between the ages of 6 and 9 years. It was uncommon before 5 years or after 20 years in this series.

History of Parental Syphilis—Owing probably to incomplete observation of the families of these patients, a definite diagnosis of syphilis in the parents was made in but a few cases. Eight mothers and six fathers were so diagnosed. A suggestive history in the form of miscarriages or stillbirths was obtained in nine other mothers. In only one of these cases was the central nervous system involved in a parent. This was a father who died of dementia paralytica in a state hospital. Others report a common involvement of the central nervous system in the parents. Amelian reports six cases in which both parents had dementia paralytica. In Frolich's³ cases dementia paralytica existed in 16.4 per cent of the parents, in an additional 13 per cent, tabes or cerebrovascular syphilis was demonstrated. Klauder and Solomon⁴ in twenty-three cases found neurosyphilis in three parents.

Syphilis in Siblings—In only two cases was definite evidence of hereditary syphilis found in a living sibling. A history of miscarriages and stillbirths was very common in this series. In no case was even suggestive evidence of involvement of the central nervous system found in a sibling. Klauder and Solomon⁴ in their series had a brother and sister with juvenile dementia paralytica.

Symptomatology—The symptoms that caused these patients to come to the hospital were much the same as those mentioned by other writers. The symptomatology in patients at the adolescent age was similar to that found in adults. In the younger group, that is, the preadolescent, the symptoms were in many ways unlike those in adult cases. Epileptic seizures have been recorded as common occurrences by others in juvenile dementia paralytica. They were not common in this series, being found in only five cases. Twenty-five of the patients were markedly disoriented or demented, five were mildly so, and one showed no mental change at the time of diagnosis. The various symptoms, such as hallucinations, euphoria, delusions and irritability, as found in adult dementia paralytica, were found in most

Studies and Contributions from the Department of Dermatology and Syphilology, University of Michigan Medical School, service of Dr. Udo J. Wile.

of those cases, especially in those showing marked degeneration. Disturbances of memory and retardation in school were outstanding symptoms.

Objective Signs—The following changes were found in these cases. Changes in the retina were present in eleven, chiefly in the form of disseminated choroiditis, with optic atrophy in four. Hyperactive reflexes, especially the knee jerks and achilles jerks, were found in most cases, the Babinski sign in four, evidence of an old hemiplegia in two, and incontinence of urine and feces or both in five cases. Though the speech could not be accurately tested in many because of the age, a defect was noted in twelve cases. This varied from a mild slurring of the r's to complete inability to speak.

Klauder and Solomon⁴ mention that the stigmas of congenital syphilis were rare in their cases. In this group stigmas were fairly common. Sixteen of the patients had one or more of the Hutchinson triad. Thirteen had hutchinsonian teeth and four had or had had interstitial keratitis, but eighth nerve deafness was not noted in any case. Nearly all the other patients had one or more suggestive stigmas such as prominent bossae, anterior bowing of the tibia, high arch palate, and minor stigmas.

Laboratory Studies—The blood serologic reactions were strongly positive in all thirty-one cases. The spinal fluid serologic reactions were strongly positive in all cases in which a spinal fluid examination was made. The one case in which a spinal puncture was not done was clinical dementia paralytica. A colloidal gold curve in the paretic zone was found in twenty-six cases, a tabetic type of curve was found in four, and in one no colloidal gold test was made, owing to a bloody tap. The last case was without doubt dementia paralytica. The cases presenting curves in the tabetic zone were all clinical dementia paralytica. Juvenile dementia paralytica seems to differ in this series from dementia paralytica in adults, in which the spinal fluid almost invariably gives a curve in the paretic zone.

TABLE 1—Follow Up with Regard to Deterioration at Time of Diagnosis

Results with Therapy—Answers were received to twenty-four of the thirty-one queries sent out. Seven of the patients, or 29.1 per cent, were dead, seven, or 29.1 per cent, had an unchanged condition, eight, or 33½ per cent, were worse, and two, or 8.3 per cent, were improved.

From table 1 it will be seen, as would be expected, that the results were more unfavorable in patients showing marked involvement at the time of diagnosis.

From table 2 it will be seen that slightly better results were found in patients over 20.

Most of the fifteen patients who did not receive malaria therapy were treated with the heavy metals. Most of those who received malaria also had the benefit

of heavy metal therapy. Of those who received malaria an answer was received from fourteen, two, or 14.2 per cent, were dead, four, or 28 per cent, were unchanged, six, or 42.6 per cent, were worse, and two, or 14.2 per cent, were improved. Of the fifteen who did not receive malaria, an answer was received in ten cases, three, or 30 per cent, were unchanged, two, or 20 per cent, were worse, and five, or 50 per cent, were dead. The group that received malaria were in somewhat better mental condition at the time of diagnosis,

Institution	0	2	0	0	0

which may account for some of the statistical improvement. Only one patient is now able to cope with his environment at this time, a man aged 26 at the time of diagnosis in 1927. He had diagnostic evidence of congenital syphilis in the form of Hutchinson teeth, prominent bossae, anterior bowing of the tibia, and a high arched palate. Clinically and by laboratory studies he had dementia paralytica in 1927. He had had considerable intravenous and intramuscular therapy in 1919. When the diagnosis of juvenile dementia paralytica was established in 1927, he received sixteen malaria chills and began to improve shortly thereafter. He was able to return to work and has been working up to the present time with only a small amount of subsequent therapy in the form of potassium iodide by mouth and mercury rubs. The spinal fluid has remained four plus, though the colloidal gold curve has changed from a paretic to a tabetic type.

All the others about whom a report was received are dead, are living a vegetative existence in an institution or at home, or are so mentally or physically retarded as to be almost a total loss to their families and to society at large.

It is difficult to decide from such a small series what cases should be selected for this form of treatment, if any. The cases suitable for malaria treatment are those, it would seem, in which the diagnosis is made by a routine spinal fluid examination before any clinical symptoms or signs have appeared, or those in which the mental changes are very mild and have come on fairly late in adolescence or early adult life. Such cases in the juvenile type are rare.

CONCLUSIONS

1 The prognosis in juvenile dementia paralytica has been changed little if at all by the advent of malaria and other forms of fever therapy.

2 Malaria therapy prolongs life in juvenile dementia paralytica in some cases. It seems to retard the progressive dementia in a few.

3 The slight improvement that is found in a few cases does not raise these unfortunate patients to the level of social and intellectual usefulness and only adds to the burden the family or society or both must bear.

4 Malaria therapy adds very little to the prognosis in the large majority of cases and should not be used except in the rare selected cases.

MENINGOCOCCIC MENINGITIS IN CHILDREN

JOSEPHINE B. NEAL, MD

In Charge of the Division of Applied Therapy, Bureau of Laboratories,
Department of Health
NEW YORK

Meningococcic meningitis in nonepidemic periods is essentially a disease of childhood. During epidemics and sharp outbreaks, the age incidence is considerably higher. The reason for this I do not know. Table 1 shows the age incidence in more than 1,300 cases of meningococcic meningitis. The distribution by age and etiology of the other more than common forms of meningitis is also shown. Table 2 shows the distribution by age and etiology of more unusual types of meningitis. Table 1 shows that by far the largest number of these cases of meningococcic meningitis occurred in the first year of life. It is at this age that the diagnosis is most difficult in the early stages of the disease and the case fatality is the highest. The same statement applies in a modified degree to children in the second year of life.

The clinical picture in older children follows closely that in adults. This is so familiar that no extended discussion is necessary. It may be well to point out, however, that in these older patients the disease may be divided into three types:

1. The usual type, in which there may be a transient bacteremia indicated by a petechial or even macular rash, which appears early and soon fades but in which a positive blood culture is only rarely obtained.

2. The septicemic type, in which a septicemia precedes the meningitis by a varying length of time and may persist after the meningitis has developed. In this type of case, the hemorrhagic rash shows a tendency to persist and recur in crops, and a blood culture can be obtained.

3. The fulminating type, in which there is an unusually violent onset with an overwhelming infection, usu-

ally both of the blood stream and of the meninges. In this type, death may occur within a few hours. Reference must also be made to meningococcic septicemia occurring without meningitis. This discussion applies particularly to older children and adults.

In the first and even in the second year of life, it is my impression that the fulminating type is rather uncommon, and so also is septicemia. The early symptoms in infants do not as a rule suggest an involve-

ment of the central nervous system. The onset, while usually sudden, is not so abrupt as in older patients. There are almost always signs of involvement of the gastro-intestinal tract, vomiting being common and greenish, slimy stools almost constantly present. There is an irregular fever higher than one would expect in gastro-enteritis. Convulsions may occur at the onset but not more frequently than at the beginning of other acute infections in infants. There is usually a tension or bulging of the fontanel. A Brudzinski sign may

sometimes be elicited rather early. Usually it is not until the disease is fairly well advanced that there develop stiffness of the neck and back or opisthotonos, changes in the reflexes, strabismus or severe convulsions. Debre once said "In times of epidemic think of meningitis and do a lumbar puncture in every infant sick without apparent cause." This advice, it seems to me, is even more applicable in times when there is no epidemic, for at these times, in my experience, meningitis is more likely to occur in young infants and the consideration of a diagnosis of meningitis is not so likely to occur to the physician.

There are many conditions and diseases in which signs and symptoms develop resembling a meningitis. It can be determined whether or not meningitis is present only by a lumbar puncture and the examination of the spinal fluid. If meningitis is present, the kind can be determined only by a cultural examination of the spinal fluid, except in the case of tuberculous meningitis. In this disease the diagnosis may be established by the demonstration in the smear of acid-fast bacilli. Table 3 shows the characteristics of the spinal fluid in the various forms of meningitis and in certain diseases in which a differential diagnosis must be made.

It is important to emphasize that every spinal fluid withdrawn should be completely examined. Smears from clear fluids should be stained by the Ziehl-Neelsen method, smears from cloudy fluids by the Gram method, and smears from hazy fluids by both methods. In the case of purulent meningitis, only a tentative diagnosis can be made from the examination of the stained smear, as the organisms in spinal fluids are occasionally pleomorphic and the gram-positive organisms may decolorize. A careful study of the cultures is therefore necessary. This should be made on a variety of media, including those suitable for anaerobic growth. Cultures are not to be considered negative until they have been incubated for at least two weeks. All cultures isolated should be thoroughly studied to determine as nearly as possible their exact classification and type.

It has recently been shown that the tubercle bacilli in spinal fluids may be successfully cultured on Bordet-Gengou medium, even when they are so few in number that they cannot be demonstrated in the smear. This method is more satisfactory than the inoculation of guinea-pigs. The strains of the meningococcus have been variously grouped by different workers. Generally, Gordon's division into four groups has been followed. Groups 1 and 3, which are most commonly present, at least in New York City, show more or less close relationship by agglutination and absorption. There are always a certain number of strains that do not fall definitely into any one of these groups. For these reasons, a polyvalent serum is more satisfactory than a monovalent serum.

In purulent meningitis the cell count is of doubtful value. In the first place, it is difficult to obtain a uniform mixture of the cells through the fluid, as the cells settle out rapidly. Again, if the fluid is collected in successive tubes there is a marked variation in the cell count in the different specimens. For these reasons, comparisons of the cell count on succeeding days are

If the patient is not of the septicemic type with a positive blood culture, we think serum is indicated only intraspinally. Patients suffering from meningitis are acutely ill and deserve to be disturbed as little as possible. Serum is a foreign protein, more or less toxic, and the injections of unduly large amounts may have distinctly unfavorable effects on the patient. For these reasons, we are opposed to the indiscriminate administration of serum intravenously and intramuscularly and to the intraspinal administration of the serum every twelve to eight and even every six hours, as is sometimes advocated. It is not known in exactly what way the serum acts. It is not bactericidal and it probably functions mainly by increasing the phagocytic power of the cells. It can do this in quite low dilution. It has been shown that serum injected intraspinally is not entirely eliminated for about twenty-four hours. It therefore seems likely that, when too frequent lumbar punctures are done, cells at the maximum of their fighting power are removed and the purpose of the treatment is defeated. It is our custom, whenever a lumbar puncture reveals a cloudy or hazy spinal fluid, to give

TABLE 3—*Characteristics of the Spinal Fluids in Various Conditions*

Meningeal Condition	Amount Cc	Appearance	Cytology	Bacteriology	Albumin	Globulin	Sugar
Normal	5-10	Clear	5 to 10 cells mononuclears	Negative by smear and culture	±	±	Normal
Meningism	20-50	Clear	5 to 10 cells occasionally more mononuclears	Negative by smear and culture	± to +	± to +	Normal

Purulent meningitis	20-60	Hazy to purulent	Indefinitely high polynuclears	Infecting organism by smear and culture	+ to ++++	+ to ++++	May be normal at onset decreases as disease advances

likely to be of no value and even misleading. The protein requires no discussion. The sugar content is important. Early in meningococcic meningitis the sugar may be normal, as the disease progresses it becomes decreased or even absent. If the patient improves, the return of the sugar to normal usually parallels the improvement in the patient's condition. A fall in sugar content not infrequently foretells an exacerbation.

The value of serum in the treatment of meningococcic meningitis has been generally accepted for nearly thirty years. In spite of this, there is still a wide divergence of opinion in regard to its proper administration. Certain factors contribute to the confusion of ideas. In the first place, no absolutely uniform rules can be laid down for treatment, since the disease varies so widely in its manifestations in different outbreaks and at all times in individual patients. Secondly, there is, unfortunately, no absolutely reliable laboratory test for the therapeutic value of the serum. For this reason, at times serum of poor quality has been used with resulting failure of proper response on the part of the patient. Under these conditions, in desperation physicians have resorted to larger and larger quantities of the serum in the hope of obtaining better results.

From an experience covering nearly twenty-five years, my associates and I are convinced that the best results are obtained by moderation in the use of the serum

immediately antimeningococcus serum intraspinally. Further administration will depend on the examination of the spinal fluid, but all cases are treated on the assumption that they are meningococcic meningitis until some other organism is isolated. We inject antimeningococcus serum intraspinally about once in twenty-four hours after thoroughly draining the subarachnoid space. It occasionally may happen that the spinal fluid is under so greatly increased pressure that a lumbar puncture may have to be performed more often than once in twenty-four hours for relief of pressure. In this condition, of course, serum must be given following each puncture. The dose of serum is usually about 20 cc if as much or more fluid has been withdrawn. Occasionally a larger dose than this is used. The serum should be warmed to body temperature and administered slowly by gravity. The daily administration of the serum is continued until at least two successive fluids show no organisms by smear or culture. If at this time the patient is fairly well clinically, the administration of the serum is stopped, at least temporarily. The lumbar punctures are continued every twenty-four or forty-eight hours for a varying length of time to relieve the pressure and to make sure that the fluid is sterile.

If block develops—complete or partial—the subarachnoid space must be drained and the serum administered either by cisternal or by ventricular puncture. If the

fontanel is still open, ventricular puncture is to be preferred to cisternal, as it is safer and more effective, since the block may be high. Sometimes block may be relieved by the cautious injection after lumbar puncture of air, physiologic solution of sodium chloride, or serum. After this method of treatment is begun, lumbar punctures should be performed at intervals to see whether the block has been relieved. In the septicemic type of case, serum should be administered intravenously as well as intraspinally. Daily injections of from 50 to 100 cc of serum diluted with an equal amount of physiologic solution of sodium chloride should be made. This should be done very slowly by gravity. A daily blood culture should be made preceding the injection of the serum so that the treatment may be discontinued when the blood stream is sterile. Occasionally, one sees cases of meningococcic septicemia without meningitis. These should be treated by the intravenous administration only of serum.

I have had very little personal experience with the new Parke Davis antitoxin for the treatment of meningococcic meningitis. The clinical picture of certain cases of meningitis indicates a rather severe toxemia. It would seem, therefore, that a serum with a high antitoxic content may be of great value, especially in this type of case.

The use of autogenous vaccine in prolonged cases of meningitis, and in the few cases which are or have become intolerant to serum, has seemed to be of value in certain instances. This vaccine should be administered both subcutaneously and intraspinally. The subcutaneous injections may begin with a dose of from 100 to 250 millions and are repeated every three or four days, the dose being gradually increased to a billion or more. The intraspinal administration should be done daily, beginning perhaps with a dose of 50 million diluted in physiologic solution of sodium chloride or in serum, if the patient is not intolerant to serum, and increasing by 50 million each day. The whole question of dosage is empirical.

We have never tried forced spinal drainage in meningococcic meningitis. We have used it in other forms of purulent meningitis but our own results have not been particularly encouraging.

Complications must be treated as they arise. Perhaps the only complication that can be successfully treated by serum is the purulent arthritis which occasionally develops. This usually subsides under symptomatic treatment, but in some instances it may be necessary to aspirate the joint and inject the serum.

Recently it has happened that a very few patients have died soon after lumbar puncture and the administration of serum. At necropsy it was found that an acute hydrocephalus had developed, so that when the equilibrium of the spinal fluid was disturbed by the withdrawal of fluid there had been a herniation of the cerebellum with compression of the medulla. In these cases there had been unusually excruciating headache with or without indications of papilledema. In such instances it is advisable to give a hypodermic of 3 grains (0.2 Gm) of caffeine preceding the spinal tap. This will reduce the extreme intracranial pressure, as shown by Foster Kennedy and his collaborators, and tend to prevent this occurrence.

General treatment of meningococcic meningitis is that of any severe acute infection. It is important that the patient have adequate rest, and for this purpose sedatives must be given as indicated. Morphine hypodermically should not be used, as it increases the intra-

cranial pressure. A sufficient amount of nourishment must be given, preferably in small amounts at frequent intervals. The fluid intake must be maintained by clysis if necessary. The fluid should be of such a nature as to overcome the tendency to acidosis. Care must be taken to see that retention of urine is not neglected. Proper elimination by the bowels may be accomplished by small doses of magnesia magna combined with enemas.

While the case fatality in children of the first or even the second year of life is high, that between the third and fifteenth year is the most favorable of any age group. I would emphasize again the importance of a conservative method of administering the serum. This opinion is based not only on our own experience but also on that of a number of hospitals that have followed this method.

Foot of East Fifteenth Street

ABSTRACT OF DISCUSSION

DR. BRONSON CROTHERS, Boston. There are one or two points that seem to me worth thinking about. Dr. Neal says that ventricular puncture is more effective and less dangerous and is also higher than cisternal puncture, that is the assumption is made that the serum in the ventricle is above that put into the cistern. Anatomically, that is correct, but it does not enter the subarachnoid space any higher than that put into the cistern. I think that cistern puncture is extremely dangerous in meningitis, because it is very difficult to tell where the needle is. However, I think one gets the serum where one wants it rather better by the cisternal than by the ventricular route, provided one can get in. That brings up one other point. If neither the cistern puncture nor the ventricle puncture throws the serum into the supratentorial space, it does seem to me logical in occasional cases to introduce the serum into the supratentorial subarachnoid space. Another point is the question of using intraspinal vaccine. I am not expert in this matter, but it seems to me illogical in theory. I should like to know from Dr. Neal whether she feels that the results are so good that she is willing to keep on with that with some enthusiasm in spite of its apparently illogical character.

DR. EMILY P. BACON, Philadelphia. The high incidence of meningococcic meningitis in infants in Dr. Neal's series shows that there were four and one-half times as many cases in infancy as in older children. Early diagnosis and treatment are exceedingly important, but, as in many other diseases of infants, it is exceedingly difficult because early symptoms and signs are not typical. Dr. Neal has stressed that neurologic symptoms are often absent early and that symptoms common in gastro-enteritis are often present, such as vomiting, slimy stools, high fever and marked distress. But there are points of differentiation that help in making the early diagnosis. The seasonal incidence is apt to be different and the fever in gastro-enteritis is usually not so high as in meningococcic meningitis, and yet the baby is much sicker, is more toxic, and dehydrates earlier. Also, the fontanel is depressed in gastro-enteritis, whereas almost always in infants with meningococcic meningitis the fontanel is at least tense. However, if one is in doubt, a lumbar puncture must be done to exclude meningococcic meningitis. Another condition in infants that is difficult to differentiate at times from meningococcic meningitis is infection of the upper respiratory tract with symptoms of vomiting, fever, red throat and red ears. I have recently seen these symptoms in two cases in which it was difficult to decide whether they denoted an infection of the upper respiratory tract alone or whether they were coincident with meningococcic meningitis and of minor importance. In one child, a baby of 6 months, the ears were opened three times and pus was obtained once. Lumbar puncture was not done until the tenth day, because no neurologic sign was present, except a little tenseness of the fontanel. The spinal fluid was reported to be clear but was not examined further. Three days later neurologic symptoms were more definite, the puncture was repeated, and meningococci were found in the spinal fluid.

Treatment was instituted too late. The child is developing hydrocephalus, and prognosis for cure is poor. As to treatment, most are agreed that serum is at present the best therapeutic agent and that intrathecal treatment given every twenty-four hours is best for the patient as a rule. If the infant is seen early in the disease, associated intravenous therapy is indicated, provided there is available a doctor skilled in intravenous therapy in infants.

DR. JOSEPHINE B. NEAL, New York. I have practically nothing to say in closing except with regard to the point Dr. Crothers brought up. The vaccine is still being used in some of the chronic cases and in cases in which intolerance to serum has developed. My idea in giving vaccine intraspinally was to get a reaction intermediate between the slow response that is obtained when vaccine is given subcutaneously and the rather severe reaction that is obtained when vaccine is given intravenously. It is known that laboratory animals can be immunized by vaccine given either subcutaneously or intravenously. While I do not think that it is at all sure that those patients who recovered following this method of treatment recovered on account of it, I am still continuing to use it. Perhaps sometime there will be enough patients with sufficiently definite results to make certain whether or not it does do any good.

CLINICAL SIGNIFICANCE OF CHOREA AS A MANIFESTATION OF RHEUMATIC FEVER

A STUDY IN PROGNOSIS

T. DUCKETT JONES, M.D.

AND

EDWARD F. BLAND, M.D.

BOSTON

The occurrence of uncontrolled and purposeless movements in childhood involving primarily the extremities but affecting in severer grades voluntary muscles elsewhere, and for which there exists no demonstrable neurologic or psychologic background, is accepted as so-called Sydenham's chorea. The close association between this symptom complex, known as chorea, and rheumatic fever has been recognized for many years. Not only the frequency of choreiform movements in patients exhibiting symptoms and signs of rheumatic fever but also the high familial incidence of the two, together with the similarity in seasonal variation to be commented on later, is sufficiently striking to suggest a close interrelation between these two conditions. Furthermore, the frequent association between chorea and heart disease of the rheumatic type lends additional supporting evidence that Sydenham's chorea is probably a manifestation of rheumatic fever. Proof of this relationship, however, must await the establishment of the etiology of the two. It is our purpose in this paper to present certain data that we believe are important in an evaluation of the clinical significance and prognostic implication of this as yet imperfectly understood symptom complex, together with a consideration of the apparent discrepancies between the present study and previously published reports.

Many authors state definitely that, omitting habit spasm and purposeless movements of evident neurogenic origin, it is safe to consider choreiform movements as a part of the rheumatic syndrome. Coombs,¹

Poynton and Schlesinger,² and Findlay³ have expressed this opinion. Concerning the exact role, however, which chorea plays as a manifestation of rheumatic fever, there has been no general agreement. The literature is voluminous and the scope of this paper such that an exhaustive review is not indicated. Only the more commonly accepted opinions will be reviewed.

An interesting comment concerning the status of chorea was written by Bouteille⁴ in 1810:

Tout est extraordinaire dans cette maladie, son nom est ridicule, ses symptômes singuliers, son caractère équivoque, sa cause inconnue, son traitement problématique.

An extensive monograph on the subject was written by Osler⁵ in 1894. His review of the knowledge concerning not only chorea minor or Sydenham's chorea but also other types of choreiform movement is excellent, and his teachings are well known to students of the disease as well as to many practicing physicians. In the forty years since the publication of his treatise there has been little added to the more fundamental knowledge of this distressing condition. Osler⁵ left little to the imagination concerning the importance of chorea in the development of heart disease of the rheumatic type, as is clearly shown in the following quotation:

The extraordinary frequency with which mitral valvulitis is met with in fatal cases is remarkable. There is no known disease in which endocarditis is so constantly found, post mortem, as chorea, it is exceptional to find the heart healthy.

An abundance of clinical material to support this thesis was presented, a criticism of which will be presented later. Relatively the same opinion was also expressed recently by Swift,⁶ who stated that "chorea is one of the grave manifestations of rheumatic fever in childhood."

Mackie⁷ from an analysis of 393 cases of rheumatic fever and eighty-nine cases of chorea found that there was no significant difference between these two types of rheumatic infection as far as subsequent heart disease was concerned. Strong⁸ reported a slightly higher incidence of rheumatic heart disease in cases of chorea than in cases of rheumatic fever. He also collected 2,359 reports of cases of chorea from the literature, in 953, or 40.3 per cent, of which rheumatic heart disease was noted. The incidence of heart disease in his own series was 45 per cent, while that for rheumatic fever was 38 per cent, a figure which may well be considered low in view of a large literature to the contrary.

A less drastic view was expressed by Coombs,¹ who found rheumatic heart disease in only 44 per cent (at the time of onset) of patients with chorea as opposed to 75 per cent in rheumatic subjects who exhibited joint pains. He further stated that, of the subjects whose first manifestation of rheumatic fever was chorea, only about 3 per cent failed to survive the first decade. But when the average duration of cases that have ended fatally is considered, figures relative to heart disease are practically the same as those for the group of patients whose condition began with rheu-

matic fever Coombs¹ stated that chorea usually occurs in cases of the mildest grades of rheumatic infection. As a result of an analysis of the records of 180 children with rheumatic infection, Marshall⁹ expressed the opinion that in many patients with severe chorea with frequent recurrences carditis never develops, and "one sometimes wonders if this is due to a different causative agent." Findlay,³ in a recent monograph in which he gave his observations over a period of years on 701 rheumatic children, expressed much the same opinion. He did not find rheumatic heart disease so commonly in patients with chorea (50 per cent of hospitalized patients with chorea) as in those with arthritis (75 per cent). He further stated that he had never seen a child die of chorea in whom the heart was not affected, and in those cases he blamed the myocardium for the fatal issue. In discussing the differences between the cases of rheumatic infection characterized by arthritis and those characterized by chorea (chiefly in considering the relative rarity of pericarditis and subcutaneous nodules in patients with chorea), this author expressed the opinion that "either all cases of Sydenham's chorea are not rheumatic in origin or different strains of the rheumatic virus are responsible for the two manifestations."

Such are a few of the varied opinions that have been expressed regarding the relationship between chorea and rheumatic fever. It is evident that there are differences of opinion, but there is general agreement that the relationship is more than coincidental. Hence any one observing a considerable number of instances either of rheumatic fever or of chorea will frequently encounter the other condition. The only exception to this association occurs in the older group of patients with rheumatic fever after the second decade, in whom chorea is uncommon.

At the present time one rarely observes a case of the violent chorea which gave rise to the term chorea insaniens, and the exhaustive features of the condition are not encountered as commonly as a decade or two ago. Even omitting this violent but rare form of the symptom complex, it is difficult to evaluate the rôle of chorea itself as regards its effect on the heart. In the reports in the literature there have been frequent failures to dissociate the effects of chorea alone in contrast to the effect of chorea plus other evidence of rheumatic fever in the consequent development of heart disease. The case reports cited are so brief that it is difficult to conclude whether or not chorea was an important factor in the development of the pathologic condition of the heart. As may be seen from the discussion of the literature just given, the earlier observers felt that chorea was very conducive to the development of endocarditis, especially of the mitral valve, while more recent writers tend to question the seriousness of this manifestation.

Since 1921 the House of the Good Samaritan has given long bed care to more than 1,200 subjects with various manifestations of rheumatic fever (including chorea) and it has been possible to follow the course of this large group during the subsequent years. Without discrimination, any patient having any evidence of rheumatic fever or chorea has been eligible for admission. In this respect the series observed is representative of rheumatic fever and chorea in the general region of Boston. The only limitation has been

that relatively few older patients with severely damaged hearts have been admitted because of the evident poor prognosis, and there has been a preponderance of females over males (few males over 12 years), the House of the Good Samaritan having for years limited the scope of its work to the treatment of women and children.

The clinical impression of a staff of six experienced observers has been that the patients with chorea have a better prognosis than those with other manifestations of rheumatic fever. The common experience has been that many patients with chorea exhibit no evidence of rheumatic fever other than purposeless choreiform movements. Fever, elevation of the pulse rate, elevation of the white blood count and an increase in the sedimentation rate of the red blood cells have frequently been absent. It was observed that chorea could and did occur without other clinical or laboratory evidence of rheumatic fever. The appearance of other manifestations was considered indicative of generalized rheumatic fever. This idea was stressed by Finlayson¹⁰ in 1890, who suggested that short febrile attacks during chorea are due to endocarditis. Osler⁵ stated that fever is rare, save in maniacal cases, and Findlay³ noted the absence of fever in uncomplicated cases of chorea. This author further cautioned that "fever during chorea should raise the suspicion of its rheumatic origin."

MATERIAL

The data presented in this study are the result of an analysis of 1,000 consecutive cases of rheumatic fever and chorea observed for considerable periods of time at the House of the Good Samaritan in which the patients were followed for an average period of eight years from the time of the onset of the disease. There have been numerous readmissions, and two thirds of the follow-up work has been carried out by us in cardiac clinics of the House of the Good Samaritan and the Massachusetts General Hospital. The larger part of the remaining patients have been followed by Dr. Paul W. Emerson of the Children's Hospital, to whom we are indebted for data. The information on a smaller number of cases has been obtained from the Boston City Hospital and through the courtesy of private physicians. The scope of this report deals only with that portion of the data which is pertinent to chorea. Analysis of the series as regards rheumatic fever will be presented at a later date.

There has been a decided effort to omit all cases of choreiform movement other than those of the Sydenham type. While this may be difficult in certain cases, it is our opinion that this series represents as true a group of patients with Sydenham's chorea as is possible with the present diagnostic knowledge. While it is admitted that there may be a small percentage of error, it is not sufficiently large to render the data unreliable. As seen in chart 1, the seasonal variations of the onset of chorea and of rheumatic fever in this series exhibit a comparable similarity. The use of data assembled from seasonal variations alone may be fallacious with regard to the question of etiology, but the similarity here exhibited, in addition to other data to be presented, warrants consideration of some similar factor common to the two groups. The graph shown is very similar to that published by Findlay,³ despite the fact that the seasonal incidence of such rheumatic manifestations in

9 Marshall, Robert. Review of 180 Children Suffering from Rheumatism, Chorea and Carditis. *Arch. Dis. Childhood* 3: 28 (Feb.) 1928.

Great Britain is different from that in the United States. The age of the patients herewith reported was largely from 8 to 16 years (although a small percentage were older). In chart 2 are given the data regarding the duration of observation following the onset of symptoms in 482 cases.

Chorea has been considered in this analysis as a single manifestation of rheumatic fever. Fever, save during periods characterized by violent choreiform movements, frequent nosebleeds, joint pains, pericarditis, subcutane-

Chart 1—The seasonal variations in the onset of chorea and of rheumatic fever, including recurrences in 671 instances of chorea and 1,209 instances of rheumatic fever.

ous nodules, erythema multiforme, and various laboratory evidences of infection have been considered as other manifestations of rheumatic fever. We believe that it is only after detailed studies of large groups of cases have been carried out over a considerable period of observation that the true significance of chorea as a manifestation of the generalized disease rheumatic fever can be evaluated.

ANALYSIS OF DATA

As just stated, chorea has been analyzed as a single manifestation of rheumatic fever. For the purpose of this study the patients who have had chorea are grouped in three main divisions:

GROUP 1—Chorea. Here are included all the patients observed over an average period of eight years who have exhibited frank choreiform movements. As may be seen from chart 3, this is a large group (482) consisting of nearly 50 per cent of the total series of 1,000 rheumatic patients. This is not surprising, since chorea is a common condition, and indeed it has been commented on by Osler,⁵ Coombs,¹ Findlay,³ and others as being the most common single manifestation of rheumatic fever.

GROUP 2—Chorea Associated with Other Manifestations of Rheumatic Fever. Over a period of eight years nearly three fourths (348, or 72 per cent) of all the patients with chorea at some time exhibited other manifestations of rheumatic fever. This group will be subdivided later for further consideration.

GROUP 3—Chorea Not Associated with Other Manifestations of Rheumatic Fever. While it is difficult to be absolutely certain that no other manifestations of rheumatic fever occurred during an eight year period, the search has been as exhaustive as possible. A number of admissions both at the House of the Good Samaritan and elsewhere have been reviewed and in

most instances frequent and detailed histories were taken. If actual low grade rheumatic fever was present at any time, we believe that it did not reach a clinical level. We are cognizant that such conditions are occasionally present and recognize the fact that rheumatic heart disease does develop in the absence of a history of rheumatic fever. In this group of slightly over one fourth (134, or 28 per cent) of the total group of patients with chorea no frank evidence of other manifestations of rheumatic fever could be elicited.

INCIDENCE OF HEART DISEASE

Some indication that chorea may not be readily associated with the development of rheumatic heart disease is obtained from chart 4. Rheumatic heart disease was found in 54 per cent of the patients with chorea (259 of 482). This figure is in general agreement with statistics found in the literature. Osler⁵ found this incidence to be 51 per cent, Marshall⁶ 60 per cent, Mackie⁷ 51.5 per cent, Poynton¹¹ 50 per cent, and Findlay³ 50 per cent. Strong⁸ (45 per cent), Wallace¹² (41.5 per cent), and Abt and Levinson¹³ (32 per cent) reported slightly lower figures. As previously noted, in 2,359 instances of chorea collected from the literature by Strong,⁸ heart disease was present in 953, or 40.3 per cent. It is difficult to determine from the published reports the period of observation of many of these studies. Coombs¹ reported that eventually rheumatic heart disease developed in 76 per cent of his patients with chorea, but again the period of observation was not given. In our series the incidence of heart disease in a comparable sized group (518) of patients with rheumatic fever without chorea over a similar average period of eight years was 86 per cent (447 instances). The criteria for the diagnosis of rheumatic heart disease were those advocated by the American Heart Association.¹⁴ Throughout these studies and in the accompanying charts the term potential rheumatic heart disease is used to denote the absence of clinically demonstrable heart disease in a patient who has had either rheumatic fever or chorea. This differ-

Chart 2—Duration of period of observation from the onset of chorea or of rheumatic fever for the 482 patients with chorea. The average duration in this group was eight years.

ence between 54 and 86 per cent is striking and indicates definitely a lower incidence of rheumatic heart disease when chorea is a part of the syndrome of rheumatic fever. Since the incidence of heart disease in

the patients with rheumatic fever compares favorably with that in numerous series as reported by capable observers, the percentages in both groups must be given serious consideration

In an attempt to evaluate this seeming discrepancy between the groups of patients with chorea and those with rheumatic fever, the incidence of heart disease was determined in those with chorea who had also exhibited other manifestations of rheumatic fever. As shown in chart 4, the group consisted of 348 subjects and heart disease was found in 255, or 73 per cent, of the group. It is clear that manifestations of rheumatic fever other than chorea influence strongly the development of rheumatic heart disease. The discrepancy then in the incidence of heart disease in the patients with rheumatic fever (86 per cent) as compared with the patients with chorea (54 per cent) seems to be largely in those patients of the latter group whose only rheumatic manifestation has been chorea, instances of the so-called pure chorea. Further analysis proves this to be correct.

INFLUENCE OF CHOREA ON THE DEVELOPMENT OF RHEUMATIC HEART DISEASE

Of the 482 subjects observed to have had chorea, 318 (66 per cent) exhibited only chorea as a manifestation of rheumatic fever at the onset, an average of eight years prior to this analysis. The analysis of this group, shown in chart 5, from the point of view of the influence of chorea on the development of rheumatic heart disease further stresses the importance of manifestations of rheumatic fever other than chorea. In this group 134 (42 per cent) who exhibited only chorea as evidence of rheumatic fever at the onset were found at the end of eight years to have exhibited no other evidences of rheumatic fever. In this group there is a striking absence of rheumatic heart disease. For

Chart 3—Analysis of group of patients with chorea

the sake of clarity in the subsequent discussion, and in the absence of a better term, we have designated this as the group of patients with "pure" chorea. In only four instances (3 per cent) was rheumatic heart disease found, and in view of the frequency with which one encounters heart disease of the rheumatic type in adult life without a previous history of rheumatic fever, it is surprising that the incidence here is not higher. As will be discussed later, a number of these patients had more than one attack of chorea, and despite this there remains the surprisingly small percentage with heart

disease (3 per cent). Among the 184 subjects (58 per cent) in whom other manifestations of rheumatic fever developed subsequent to chorea, the incidence of rheumatic heart disease was 80 per cent (147), a figure which approximates the incidence (86 per cent) of rheumatic heart disease in the group of patients with rheumatic fever uncomplicated by chorea (chart 4). It may be well to point out that it is in this group (chorea and subsequent rheumatic fever) that one finds

Chart 4—Incidence of rheumatic heart disease following chorea and rheumatic fever. The white columns indicate the cases of potential rheumatic heart disease and the black columns the cases of rheumatic heart disease. The term potential rheumatic heart disease is used to denote the absence of clinically demonstrable heart disease in a patient who has had either rheumatic fever or chorea.

the severer manifestations of rheumatic fever. This suggests that when manifestations of rheumatic fever occur subsequent to chorea, the patient is very liable to follow the usual course of the subject with rheumatic fever alone.

In the remaining 164 (34 per cent) of the group of 482 patients with chorea, heart disease was found in 66 per cent (108 instances). This group represents those patients in whom chorea occurred subsequent to the onset of rheumatic fever. In other words, chorea occurring during the course of rheumatic fever is not so commonly associated with the development of rheumatic heart disease as is the case when only other manifestations of rheumatic fever are present. It seems then that chorea is more commonly found during the course of mild rather than of severe rheumatic fever. This feature will be discussed in more detail later.

Thus, as a factor in the development of rheumatic heart disease it appears that other manifestations of rheumatic fever are far more important than chorea. Uncomplicated chorea seems to play but a small part, whereas the combination of other evidences of rheumatic fever in addition to chorea results in a lesser incidence of heart disease than is found in patients with rheumatic fever uncomplicated by chorea. It is little wonder, therefore, that some observers, as previously reported, have questioned the rheumatic origin of chorea or have felt that more than one agent may be involved.

RELATION OF THE NUMBER OF ATTACKS OF CHOREA TO THE DEVELOPMENT OF RHEUMATIC HEART DISEASE

If chorea is one of the grave manifestations of rheumatic fever and definitely conducive in its own right to the development of rheumatic heart disease, one would expect the number of attacks definitely to increase the likelihood of the occurrence of rheumatic heart disease. In discussing this feature, Findlay³ noted

that choreiform movements were not of serious prognostic importance. Marshall⁹ also noted the failure of the number of attacks to influence appreciably the development of rheumatic heart disease. In table 1 may be seen the analysis of our series of cases in this regard. While the patients with clinically demonstrable heart disease show a slightly higher percentage of instances in which there was more than one attack of chorea than do the patients without heart disease, the differences are not sufficiently striking to be given serious consideration. This is especially true since it has been clearly demonstrated in this series that the other manifestations of rheumatic fever far overshadow chorea as the important factor in the development of rheumatic heart disease.

Further analysis of the comparative number of recurrences or recrudescences of rheumatic fever and of chorea has been made of the 348 subjects comprising the group of patients with chorea and other manifestations of rheumatic fever. This is shown in table 2. When chorea has been more frequent than other signs and symptoms of rheumatic fever, rheumatic heart disease and potential rheumatic heart disease are found with the same frequency (34 per cent as opposed to 35 per cent), when there is the same relative number of recurrences of each, the incidence of potential rheumatic heart disease is somewhat higher (41.9 per cent in contrast to 34.9 per cent). As might be expected, rheumatic heart disease is found slightly more frequently (30.9 per cent as compared with 22.5 per cent) when the recurrences of rheumatic fever outnumber those of chorea. Here again, as is true of the influence of the number of attacks of chorea on the development of rheumatic heart disease, no striking variations are noted. These results strengthen our belief that the severity of rheumatic fever is the principal factor of importance in the development of rheumatic heart disease.

Chart 5—The influence of chorea (with and without other manifestations of rheumatic fever) on the development of rheumatic heart disease

COMPARISON OF FREQUENCY OF SEVERE MANIFESTATIONS OF RHEUMATIC FEVER

Little explanation is needed other than to comment on the evident variation found between the patients with rheumatic fever (518), and those with chorea and other manifestations of rheumatic fever (348), concerning the frequency of the manifestations as shown in chart 6. Precordial pain (with omission of the mild pain often found associated with an effort syndrome) congestive failure and pericarditis are man-

ifestations of rheumatic fever that have serious prognostic importance. It is significant that these three manifestations of perhaps gravest import are found only half as often in patients with rheumatic fever who have had chorea as compared with the patients who have had rheumatic fever unassociated with chorea. This alone is sufficient to warrant the assumption that chorea is a relatively mild manifestation of rheumatic fever. Further, the greater number of these severe

Chart 6—Comparison of the frequency of occurrence of severe manifestations of rheumatic fever in patients with rheumatic fever without chorea (black columns) and patients with chorea and other manifestations of rheumatic fever (white columns)

manifestations of rheumatic fever are found in that group of patients having only chorea at the onset, and subsequently becoming more definite rheumatic subjects. The fact that pericarditis is rarely seen in cases of chorea was commented on by Osler.⁵ More recently there has been expressed a distinct impression that the association is not uncommon. The literature has been reviewed and criticized by Findlay,³ who failed to find this frequent association. In our experience pericarditis has rarely been associated with chorea.

Subcutaneous nodules are generally acknowledged to be a manifestation of severe rheumatic fever. While we do not agree entirely with the expressions found in the literature of the necessarily serious prognostic importance of the appearance of these nodules, it must be admitted that they usually do occur in cases of severe rheumatic fever. We have observed the appearance of nodules on rare occasions in patients without rheumatic heart disease, as has also Poynton.¹¹ It is not surprising then that nodules are more common in the patients with uncomplicated rheumatic fever.

The frequency of auricular fibrillation may also be cited, but it is not included in the chart. The frequent association of this arrhythmia with mitral stenosis is well known. Here again the incidence was low in the patients with chorea and rheumatic fever, being found in only sixteen patients (4.6 per cent) as opposed to forty-five patients (8.7 per cent) with rheumatic fever only.

Prolongation of the auriculoventricular conduction time as noted in electrocardiograms is commonly found during the course of rheumatic fever. It is not necessarily a severe manifestation but is usually considered to indicate the presence of active cardiac disease. The frequency with which this is found depends largely on the diligence with which it is searched for in cases of rheumatic fever. Tracings have been made (only during the past four years of observation) in much the same routine manner in the two groups. The fig-

ures, which will be cited presently, are hence comparable for the groups considered but do not express the true incidence of this abnormality in the series. It is interesting that the patients with rheumatic fever without chorea showed this abnormality twice as often (forty-three instances, 8.3 per cent) as the patients with chorea and rheumatic fever (thirteen instances, 3.7 per cent).

Since the group of 134 patients with uncomplicated chorea failed to exhibit any of these severe manifestations of rheumatic fever, this group does not appear in chart 6.

It is our opinion that these observations strongly indicate that if chorea is found in association with other evidences of rheumatic fever the rheumatic fever is likely to be mild. Conversely, in cases of general rheumatic fever without chorea the rheumatic fever is more frequently severe, and the severe manifestations of rheumatic fever are twice as likely to occur in the absence of chorea.

PROGNOSTIC SIGNIFICANCE OF CHOREA

After an average period of eight years 28 per cent (134) of the group of patients with chorea have remained free from rheumatic fever. Further, as has been shown (chart 4), 46 per cent of this total chorea group failed to exhibit clinical evidence of rheumatic heart disease. In this group the factor of importance has been demonstrated to be the presence of manifestations of rheumatic fever other than chorea (chart 5). In addition those subjects with chorea and other manifestations of rheumatic fever have severe manifestations of rheumatic fever only half as often as the patients with rheumatic fever without chorea (chart 5). This forces us to conclude that chorea cannot be of as serious prognostic importance as other manifestations of rheumatic fever. This is also shown in chart 7, which gives the death rates of the entire group of 1,000 subjects. Under three headings the comparative percentages of fatal cases are listed. Deaths which were not in any way referable to chorea, rheumatic fever or rheumatic heart disease have been omitted.

1 In the group of patients having chorea without other evidence of rheumatic fever (134), only one death occurred as a result of rheumatic heart disease.

TABLE 1—Relation of the Number of Attacks of Chorea (482 Patients) to the Development of Rheumatic Heart Disease

Number of Attacks	Rheumatic Heart Disease		Potential Rheumatic Heart Disease	
	Number of Patients	Percentage	Number of Patients	Percentage
1	113	43.6	12	2.0
2	69	26.0	60	26.9
3	38	14.7	17	7.6
4	15	5.9	12	5.4
5	11	4.2	7	3.1
6 or more	13	5.0	2	1.0
Totals	259		223	

In that patient heart disease developed without there being at any time definite evidence of rheumatic fever other than chorea. Death resulted suddenly probably from a cerebral embolus, permission to perform an autopsy could not be obtained. Three other deaths occurred (not shown in the chart: two the result of pneumonia and the third from postpartum hemorrhage). In the three latter cases there was no evidence of rheumatic fever or rheumatic heart disease at the time of death.

2 In the group of patients with chorea and other manifestations of rheumatic fever (348) fifty (14 per cent) died of associated causes. Death resulted in forty-six cases from rheumatic fever, in three from subacute bacterial endocarditis, and in one from acute bacterial endocarditis. Four further deaths resulted from unassociated causes (one automobile accident, one by drowning, one due to pneumonia and one due to encephalitis).

TABLE 2—Comparison of the Number of Attacks of Rheumatic Fever and of Chorea in the Same Patient Relative to the Development of Rheumatic Heart Disease (348 Patients)

	Rheumatic Heart Disease		Potential Rheumatic Heart Disease	
	No. of Patients	Percentage	No. of Patients	Percentage
More attacks of chorea than of rheumatic fever	87	34.2	33	35.3
Same number of attacks	89	34.9	29	41.9
More attacks of rheumatic fever than of chorea	79	30.9	21	22.5
Totals	255		83	

3 In the group of patients with rheumatic fever (518) there were 166 deaths (32 per cent) from causes associated with the disease. The large majority of these deaths (140) resulted from rheumatic fever. In eight instances death resulted from subacute bacterial endocarditis and in three from acute bacterial endocarditis. Six patients died suddenly of cerebral embolism; four died after the age of 40 of congestive failure without clinical evidence of active rheumatic fever, and in five the cause of death could not be definitely determined, though it was said to be due to heart disease. Seven further deaths occurred from unassociated causes and are not listed (two from automobile accidents, one following a ruptured appendix with generalized peritonitis, one of brain abscess, one at the time of cesarean section and two of pneumonia).

These death rates seem to present incontrovertible evidence that chorea per se does not indicate a serious prognosis. Other manifestations of rheumatic fever seem to be the determining factor as regards both the development of rheumatic heart disease and the ultimate prognosis. It may be pointed out here that those patients with chorea and other manifestations of rheumatic fever exhibiting the three more severe manifestations of rheumatic fever (pericarditis, congestive failure and precordial pain) are in the majority of instances dead. In no instance among the fifty deaths in this group was chorea present during the terminal illness (or last recurrence of rheumatic fever). This confirms our clinical impression that the severity of rheumatic fever is the prognostic point of importance in a group of young patients with rheumatic fever.

COMMENT

The prognostic significance of chorea as a manifestation of rheumatic fever has evidently been exaggerated in the past. We believe that the association between true Sydenham's chorea and rheumatic fever is too close to warrant a separation of this symptom complex from the syndrome of rheumatic fever. The statistics herein presented, as well as the voluminous literature, render this evident. Further, because of the various observations presented in some detail in this communication, we believe that chorea is evidence of the presence of mild rheumatic fever. In the absence

of other evidences of rheumatic fever, either by clinical signs and symptoms or by laboratory observations chorea seems to play but a small role in the development of heart disease of the rheumatic type

This point of view may seem at variance with established conceptions of chorea, but the data as presented confirm our contention. As mentioned previously several authors have noted the fact that in patients with chorea the prognosis is better than in those with arthritis or carditis as evidence of rheumatic fever. It is generally noted, also, that rheumatic heart disease is not as commonly associated with chorea as with the other manifestations of rheumatic fever. The separation and analysis of choreiform movement aside from other evidences of infection have been neglected in reports in the literature, and it is usually impossible from the data presented to separate the groups as we have done in this study. It is necessary to have a large group under prolonged observation and to study them from clinical and laboratory standpoints in order to evaluate the manifestations of rheumatic fever. It is probable that, if similar criteria had been used in previously reported studies, figures comparable to ours would have been obtained.

Of the seventy-three patients cited by Osler³ (many of the reports having been collected from the literature) thirty-nine definitely had rheumatic fever according to his criteria, ten others had fever, six pericarditis, two infarcts, and one nephritis. These last nineteen subjects were not considered by Osler to have had rheumatic fever, but fresh mitral valvulitis was found post mortem. On the basis of our criteria we should consider this latter group of nineteen patients as having rheumatic fever. Thus, rheumatic fever may be considered as accounting for fifty-eight rather than thirty-nine of the seventy-three deaths reported. Further cases were examples of chorea insaniens and other cases had a fatal outcome as the result of pneumonia, peritonitis and unrelated infections. By reevaluating the data presented by Osler, it is seen that rheumatic fever and not chorea seems to be the important factor in his series also.

Chorea insaniens is not commonly encountered today and in this presentation it is not considered. One occasionally sees a patient with protracted exhaustive chorea, but on the whole even this is rare and in our experience has not been conducive to the development or progression of rheumatic heart disease in the absence of other manifestations of rheumatic fever.

We are cognizant of the fact that chorea without other manifestations of rheumatic fever may have a separate etiology. This is evident from the data presented. It is also evident that in a large group of patients exhibiting choreiform movements, other manifestations of rheumatic fever are common over a period of eight years. Gerstley and his associates¹⁵ recently stated that "chorea should not be taken as an indication of rheumatic infection without other rheumatic manifestations." While this may be plausible, the answer to this difficult problem must remain indefinite until more knowledge concerning the etiology is available.

SUMMARY AND CONCLUSIONS

1 An analysis of the prognostic significance of chorea as a manifestation of rheumatic fever has been made in a group consisting of 482 patients with chorea

These patients have been compared with 518 patients presenting manifestations of rheumatic fever other than chorea

2 Over an average period of eight years, 72 per cent of the patients with chorea exhibited other manifestations of rheumatic fever while in 28 per cent only chorea was found

3 The incidence of rheumatic heart disease in the groups of patients studied was 86 per cent in the group of patients with rheumatic fever without chorea, as compared with an incidence of 54 per cent of the patients with chorea. When the group of patients with chorea was further analyzed into (1) those with chorea and other manifestations of rheumatic fever and (2) those with chorea but no other manifestations of rheumatic fever (so-called pure chorea), the incidence of rheumatic heart disease was found to be 73 per cent and 3 per cent respectively.

4 That the presence of chorea alone does not greatly influence the development of rheumatic heart disease is shown by the fact that, of 134 patients with chorea only, the incidence of heart disease was only 3 per cent, of 184 subjects who showed other evidence of rheumatic fever subsequent to chorea heart disease

Chart 7—Number of deaths in a series of 1 000 patients (in three groups) over an average period of eight years directly due to rheumatic fever (including chorea) and rheumatic heart disease

was found in 80 per cent (147), and of 164 subjects who had chorea subsequent to rheumatic fever, heart disease was found in 66 per cent (108). Thus, manifestations of rheumatic fever other than chorea are important factors in the development of rheumatic heart disease.

5 The number of attacks of chorea does not appear to influence significantly the development of rheumatic heart disease.

6 The severe manifestations of rheumatic fever (especially precordial pain, pericarditis and congestive heart failure) occur twice as frequently in patients having rheumatic fever as in those having chorea in addition to rheumatic fever.

7 Death occurred in only 0.7 per cent of the patients with uncomplicated chorea, in 14 per cent of those with rheumatic fever and chorea, and in 32 per cent of those with rheumatic fever only. Thus, the death rate is seen to increase noticeably in the groups of patients exhibiting more evidence of rheumatic fever than chorea.

8 Therefore, chorea is considered to be a mild manifestation of rheumatic fever and one in itself not especially conducive to the development of rheumatic heart disease.

TETRA-ETHYL LEAD INTOXICATION AND POISONING BY RELATED COMPOUNDS OF LEAD

WILLARD F. MACHLE, M.D.
CINCINNATI

Increases in recent years in the quantities of tetra-ethyl lead manufactured for use as an antidetonant, together with the now almost universal employment of this compound in ethyl and Q fluids throughout the world has greatly enlarged the scope of the industrial hygienic problem associated with the control of the hazards accompanying its manufacture and blending into motor fuel. Since tetra-ethyl lead added to gasoline in the maximum proportion (1:1,260) now allowed by the purveyors of the compound has been demonstrated to be free from harmful effects as far as any potential hazard resulting from the lead compound is concerned,¹ the hygienic problem is limited to those men who work with the compound prior to its addition to gasoline, and to those who may be exposed to the products of decomposition formed under certain conditions, which will be described presently. In view of the fact that in several reports in the literature no differentiation has been made between actual poisonings which occurred as a result of exposure to concentrated tetra-ethyl lead and the theoretical dangers which have been assumed to be associated with lead-treated gasoline it is well to emphasize that the cases reported in this paper, together with the accompanying symptoms, refer only to poisoning produced in the manufacture or handling of concentrated tetra-ethyl lead and its products of decomposition. Although little has been added to the symptomatology of encephalopathy due to lead poisoning since the descriptions of Tanquerel des Planches and the more recent writings of Sir Thomas Oliver in relation to exposure to the inorganic compounds of lead, the immediate connection between exposure to the volatile organic compounds and the development of characteristic acute cerebral symptoms has been so regularly observed as to justify consideration of this type of encephalopathy as a distinct clinical entity. The purpose of the present publication is to review the history of tetra-ethyl lead poisoning and its associated products of degradation and to define, on the basis of experience with seventy-eight cases, the clinical concept and the circumstances associated with its occurrence.

HISTORY

Though tetra-ethyl lead has been the subject of experiment since its discovery by Lowig² in 1852, no cases of poisoning due to it were reported in the literature until October 1924, some months after manufacture of the compound in commercial quantities was begun, when Eldridge³ referred to a series of cases reported to him by Thompson and Schoenleber. A total of 138 cases were included in their series comprising forty-nine cases seen by Kehoe in Dayton, Ohio, and seventy-one in Bayway, N. J., the remainder being seen in Deepwater, N. J. There were thirteen deaths in

these series. In July 1925 Kehoe⁴ reported a series of nonfatal cases, describing the symptomatology and clinical features in some detail from the point of view of the differential diagnosis. Shortly afterward there appeared a report by Norris and Gettler⁵ in which the results of necropsy and the chemical examination were given in four cases. These represent the first and to date the sole publications in the medical literature in which original observations have been reported. Several reports⁶ in the foreign literature have been made on the subject, but all of those writers depended for their clinical information on the aforementioned reports, some of the articles have given rise to confusion, owing to the failure on the part of the reviewers to differentiate between actual poisonings that occurred as a result of exposure to concentrated tetra-ethyl lead and the theoretical dangers accompanying the use of leaded gasoline.

Reynolds⁷ in 1928 reported a case in which there had been three weeks' exposure to tetra-ethyl lead at a manufacturing plant. At the time of examination the patient presented a parkinsonian syndrome with mental lethargy, which had developed gradually after the termination of the period of exposure. In the absence of complete information as to the clinical picture and the chemical observations at the time of onset, one hesitates to exclude encephalitis as a possible cause of the syndrome seen, particularly since this case would constitute an isolated instance of neurologic sequelae of tetra-ethyl lead intoxication.

PHARMACOLOGY

The study of the pharmacologic action of the organic compounds of lead, begun in 1878 by Harnack,⁸ is far from complete. The occurrence of poisonings due to tetra-ethyl lead in 1924 prompted investigations by Eldridge³ and later by Kehoe,⁹ who reported the toxicity of tetra-ethyl lead to be a function of its lead content rather than a characteristic of the compound. This has been held to be true of all organic compounds of lead, although Buck and Kumro¹⁰ found the minimal lethal dose for tetramethyl lead to be from 70 to 100 mg per kilogram for rats when administered intraperitoneally as compared with 10 mg per kilogram for tetra-ethyl lead and from 2 to 3 mg per kilogram for tributyl and tripropyl lead chloride. However, the vehicle used with the trialkyl lead compounds was a dilute alcoholic solution, while the tetra-ethyl and tetramethyl lead were administered in solution in olive oil. The authors reported that the absorption was slow when the material was injected in a solution of olive oil, making it difficult to compare the results. They investigated selected ionized divalent lead compounds, slightly ionized salts, complex salts, diaryl lead salts and trialkyl and tetra-alkyl salts of lead. It was noted

that the first three types of compounds behaved similarly in producing plumbism, and the trialkyl and tetraalkyl salts were again similar but differed from the first three in their tendency to produce encephalopathy.

Other investigators,¹¹ stimulated by the hope of finding a lead compound of efficacy in the treatment of malignant tumors, have studied the toxicology and pharmacology of lead triethyl acetate, hydroxide, chloride and sulphate and numerous tetra-alkyl and diaryl salts of lead.

In general the physiologic response is similar in all animals studied, including the frog, pigeon, rat, rabbit cat and dog, when fat soluble organic compounds of lead are used. Symptoms on the part of the central nervous system are striking and out of proportion to the manifestations by other systems as might be expected from the oil-soluble nature of the compound. Norris and Gettler reported the recovery of volatile lead from the brains of two of four men who died as a consequence of poisoning mainly due to the vapors of tetra-ethyl lead. In addition to volatile organic lead unusually large amounts of nonvolatile lead were found suggesting the possibility of the decomposition of tetra-ethyl lead *in situ*. Kehoe¹² was unable to find any volatile lead in the brain three and twelve hours after the application of tetra-ethyl lead to the skin of rabbits although small amounts of volatile lead were found in the blood of one and the livers of three animals. The change in composition accompanied by a loss of volatility appears to occur in a relatively short time, as for man, in two of Norris's⁶ cases in which the patients died after seventy-two hours no volatile lead was found in the brains, whereas in the two men who died within twenty-four hours the brains contained significant amounts of volatile lead. The actual time required for the degradation to occur would be expected to vary with the dosage, with the mode of administration and to a certain extent with the animals. Kehoe¹² estimated the time required for the complete decomposition and redistribution in a fashion similar to that found after exposure to water-soluble, nonvolatile lead compounds to be from three to fourteen days.

The action on the central nervous system is one of irritation. In animals restlessness and irritability are marked, combativeness may be evidenced, incoordination, ataxia and twitching occur, followed in fatal cases by convulsions and death. Sensation and consciousness are not lost except just before death.

Weakness and a fall in blood pressure have been noted. Harnack⁸ attributed the weakness to the action of lead on striated muscle, the circulatory change to action on the heart. He observed no effect on the smooth muscle of the vessels or intestine. Mason,¹³ however, attributed the changes in the blood pressure and the respiratory rate noted by him—an initial fall in blood pressure and bradycardia with an increased respiratory rate—to stimulation of the vasodilator centers and end-organs. The locus of the action of organic lead compounds in producing the fall in blood pressure which usually follows their administration has not yet

been clearly established. An increase in the respiratory rate accompanying the early stages of excitement has been noted,⁹ generally followed by a slowing, particularly in the case of rabbits, although the converse is also reported.¹⁴ Effects on the gastro-enteric tract of organic lead compounds administered parenterally are variable. Most observers, however, have noted hypermotility with a tendency to diarrhea rather than the constipation usually associated with chronic plumbism. No significant effects on the urinary tract have been noted and no experiments have been carried out to determine the possible effects on fertility. Bischoff and his associates¹¹ found tetra-ethyl lead to be no more toxic to pregnant than to nonpregnant rabbits, but a high mortality in the young was noted as a result of single large doses administered from the sixth to the fifteenth day of pregnancy. Though the progeny was weakened, no specific effect on the chorionic villi was observed following the administration of tetra-ethyl lead.

ETIOLOGY

While it is true that tetra-ethyl lead is not unique in its pharmacologic action or ability to produce a characteristic type of poisoning in man but shares this property with other organic compounds of lead which have similar physical and chemical properties, from a practical point of view it is the only compound of lead of its type in general commercial use today. Consequently the present considerations will be limited to tetra-ethyl lead or to the products of its decomposition.

Tetra-ethyl lead is a colorless oily liquid (specific gravity, 1.659) with a sweetish odor. It has an appreciable vapor pressure at ordinary temperatures, 1 liter of air at usual temperatures containing 5 mg of the material when saturated. It is insoluble in water, soluble in alcohol and acetone, and miscible with fats and oils. It is the latter property that makes available an important avenue of absorption (the skin), and the permeability of the pulmonary epithelium to the material is marked. Although the triethyl lead hydroxide and triethyl lead salts, which are the initial products of decomposition, are in the main not fat soluble, they appear to be susceptible of rapid absorption through the lungs. Considerable nasal and ocular irritation is evidenced by persons exposed even to minimal quantities of dusts of the latter compounds. Absorption from the gastro-enteric tract is variable and delayed but did occur in two cases included in this study. Vomiting and purgation were prompt.

A relatively small industrial group is potentially exposed to the hazards of the concentrated material in the form of ethyl or Q fluids. These are mixtures of tetra-ethyl lead with a halogen-containing compound such as ethylene dibromide and are in all cases colored by the addition of dyestuff to permit ready recognition of the fluid. Pure tetra-ethyl lead constitutes about 60 per cent by weight of ethyl and Q fluids. Approximately 300 to 600 men are employed in the manufacture of the fluid or in maintenance operations on the equipment in the one plant where it is now being manufactured. These men are under careful medical supervision, and exceptional precautions are taken to prevent cutaneous contact or inhalation of vapor. As a consequence, only four incipient cases with no fatalities have developed since the institution of the present

regimen in 1925. Another group of about 1,700 men is engaged from time to time in blending the tetra-ethyl lead-containing fluids into gasolines in various refineries in the United States. This group has been under the supervision of the medical department of the Ethyl Gasoline Corporation and has shown no cases of lead poisoning. In fact, recent studies by Kehoe¹⁵ have shown that the mean excretion of lead of these men is not significantly different from that of other men in industry not specifically exposed to lead. The latter group and in addition a variable number of employees in general refineries may at intervals of from one to two years be engaged for a few days in cleaning storage tanks that have contained gasolines to which lead has been added. While it is true that at the present time hygienic measures are in effect similar to those for the protection of the men engaged in the blending process and that there is no possibility of significant exposure provided the precautions are observed, the hazards are real and the safety of the men depends on constant vigilance. It may be expected, therefore, that exposure and illness will occur if the safety measures are improperly carried out or temporarily relaxed. After long standing in storage tanks, tetra-ethyl lead in commercial concentration in gasoline may undergo partial decomposition, with the formation of a variety of compounds, such as triethyl lead bro-

of the response. Alcoholism and debility may be expected to increase the likelihood of illness following a given exposure just as they influence the response to other noxious agents, but in the present group no specific susceptibility was apparent on the part of those addicted to the use of alcohol. To date, chronic intoxication resulting from exposure to tetra-ethyl lead has not been seen, consequently one can only surmise that the factors concerned with the development of plumbism from inorganic lead compounds might operate similarly in the production of chronic plumbism from the volatile organic compounds. Proper hygienic precautions and medical supervision have undoubtedly been largely responsible for the prevention of chronic plumbism, yet there is some evidence that the rate of excretion of tetra-ethyl lead is higher than that of inorganic lead compounds. Kehoe¹² found a greater proportion of the lead retained in rabbits after administration of lead chloride than after tetra-ethyl lead, indicating a greater rate of loss for the latter compound. While it is true that this higher rate would have physiologic significance only during the period preceding the decomposition of the quadrivalent compounds, it would nevertheless be of importance, as has been established for the pentavalent and trivalent compounds of antimony.

PATHOLOGIC OBSERVATIONS

Specific pathologic changes attributable to exposure to tetra-ethyl lead are not seen. Generalized visceral congestion, more marked in the brain and lungs, where it is usually associated with hemorrhage and edema has been described in rabbits by Kehoe.⁹ Those animals, as well as the dogs that were used by Eldridge,³ showed a more marked congestion in the enteric tract with frank hemorrhage. For the most part the hemorrhages are found in the duodenum and proximal jejunum in rabbits, the lymphatic aggregation in the lower ileum being most affected in dogs. In view of the fact that hemorrhages into the gastro-enteric tract have not been seen in man, that lesion must be considered characteristic only for the animals in which it has been described. Man, like animals, shows no specific lesion at necropsy. There is, however, a characteristic distribution of the severe congestion, edema and hemorrhage. Predominant lesions occur in the white matter of the brain, the vessels are engorged, in many instances seemingly blocked by an accumulation of erythrocytes that may be definitely altered, showing loss of eosinophilic stainability. Norris⁵ reported accumulations of eosinophilic material about these cellular thrombi, although scattered and partly localized degeneration of the white matter may occur without being accompanied with any cellular infiltrations or leukocytic aggregations in contiguous vessels. A second characteristic site of damage is the lung. Congestion is marked, and frank hemorrhage may occur accompanied by varying degrees of edema. Occasional hyaline thrombi are seen, with numerous accumulations of hyaline material in the interstitial stroma. Alteration of the blood occurs in some of the vessels, and accumulations of pigment laden leukocytes are common. Changes in the bronchi are not usual. There is general visceral congestion with edema except in the liver, which, however, may show degenerative changes. Degenerations of varying degree occur in the secreting tubules of the kidney, the glomeruli participate in the general vascular engorgement. The changes in the liver and kidneys, as in the heart, pancreas, adrenals and other organs represent a more or less uniform type of response to a

mid or hydroxide and diethyl lead salts. These compounds are in general of low volatility but may be dispersed as fine dusts when the storage tanks are dried before being cleaned. In eleven of the cases under observation, exposure occurred during tank-cleaning operations of this sort. Aside from evidences of irritation to the eyes and upper respiratory tract during the period of exposure, there were no differences in the apparent toxicologic action or clinical behavior in those cases as compared to others in which the exposure was to pure tetra-ethyl lead, tetra-ethyl lead mixed with ethylene dibromide, and other lead compounds.

Another group of men of varying number who may be exposed from time to time are the chemists, laboratory workers and other investigators who prepare or handle small amounts of organic lead compounds for experimental use.

Table 1 gives the incidence of poisoning in the various groups in the period from 1925 to 1930 and since 1930. Accurate figures on the incidence of poisoning prior to 1925 are not available.

The persons affected were all white men; consequently there was little opportunity for evaluating the factors of race or sex. The condition of two Italians in this series gave no indication of increased susceptibility on the part of their race. The average age of seventy-two patients was 29 years, the oldest being 55 and the youngest 16, but no difference in reaction attributable to age was noted. Variations in the magnitude of exposure almost entirely determined the severity

general noxious agent and cannot be considered characteristic. In fact, it is extremely doubtful whether one would be justified in drawing any specific conclusions as to the cause of death from the necropsy in a case of tetra-ethyl lead intoxication in spite of the somewhat characteristic localization of changes in the brain and lungs. A history of exposure to concentrated fat-soluble lead compounds together with the finding of significant amounts of lead in the central nervous system and elsewhere is essential for such a diagnosis.

SYMPTOMS AND SIGNS

The process of absorption of tetra-ethyl lead is not usually accompanied with any symptoms except perhaps a degree of nausea due to the sweetish odor of the compound. Exposure to and absorption of trialkyl compounds of lead, on the other hand, are associated with a marked degree of irritation of serous and mucous membranes. In either event the onset of symptoms of intoxication is delayed somewhat, usually for from one to three hours in the case of tetra-ethyl lead, somewhat less in the case of triethyl lead salts. As is the case with many other general poisons, the interval between exposure and the onset of symptoms varies inversely with the dose, a person in whom well marked symptoms have developed within an hour after exposure may be assumed to have had a more significant exposure than another patient in whom no definite illness develops until four or even twelve hours has elapsed. This delay in onset of symptoms is the result of at least two factors: (1) the decomposition of lead within the body with the liberation of water-soluble lead compounds and (2) the delayed absorption from either the pulmonary epithelium or the skin. Delayed absorption from the enteric tract may also occur, but this is less likely to happen because of vomiting and purgation.

A prodromal period preceded the onset of severe, acute symptoms in all cases, its duration ranged from eighteen hours to eight days, varying inversely with the magnitude of the exposure and the severity of the poisoning as did the latent period. For example, in one severe case definite symptoms of intoxication developed within an hour, progressing steadily to mania in eighteen hours. In another milder case symptoms first developed from ten to twelve hours after exposure, moderate definite symptoms were manifested for eleven days and then mania developed, this constituting the longest interval between exposure and the onset of severe symptoms seen among these patients. In this case, as in all others in which severe symptoms developed, no period of normality or significant regression of symptoms was noted prior to the onset of the severe symptoms, although slight day-to-day variation in intensity was seen. The symptoms of the prodromal period are those of the acute stage in a less serious form. In contrast to infectious lesions, little variation in the early clinical picture is seen and focal symptoms do not develop. The stimulation of the central nervous system results in insomnia, which is uniformly present, sleep is difficult broken and restless, and wild and terrifying dreams are constant. During the waking state pallor and an anxious expression are usually seen, the patient is irritable and nervous and may give evidence of delusional interpretations or a depressive mood, or his state may simulate an anxiety neurosis. Mental excitement may be marked, headache is usual and often severe, and vertigo is frequent. Evidences of meningeal irritation are absent, the spinal fluid may at times be under

increased pressure but is otherwise not remarkable. Changes interpreted as a result of alteration or damage to the peripheral nervous system were not observed, subjects able to cooperate in a neurologic examination were found to have a normal sensorium influenced somewhat toward an exaggerated response associated with the heightened general psychic irritability accompanying this there is a general increase in reflex response of the tendon and superficial reflexes being hyperactive or even exaggerated. No change in the responses of the autonomic nervous system has been noted. Reflexes not normally present were not elicited in any case. Babinski and Oppenheim signs were normal. Difficulty of vision was an occasional complaint, it appeared in all cases to be due to weakness of the extrinsic muscles of the eye. The eyegrounds were not remarkable. Anorexia, nausea and vomiting or gastric disturbance were the most constant symptoms attributable to the gastro-enteric tract, tending to be most marked in the mornings. Diarrhea occurred more often than constipation, although neither disturbance was regular or frequent. A metallic taste was complained of by many. The circulatory system is profoundly affected, the pulse rate is slow, in some cases the rate being reduced to between 52 and 56, and even in those cases in which there was marked mental excitement it did not exceed a rate of 100. Both the systolic and the diastolic blood pressures are lowered, falling in some cases as low as 80 and 40, respectively. The average systolic pressure in this series was 104, the average diastolic pressure 62, representing an average depression from the normals of 20 and 16, respectively. The maximum depressions were 53 systolic and 36 diastolic.

Weakness, tremor, muscular pains and ease of fatigue were regular or frequent complaints. Weakness was in some instances so distressing as to be made the chief complaint, only two of thirty-nine patients examined did not note it specifically. It was in all cases accompanied by ease of fatigue. Tremors, which were noted in more than half the cases, were for the most part limited to the extremities, more especially the upper extremities, although there were occasional patients with labial and lingual tremors as well. Well defined tremors were coarse and jerky, of an intention type aggravated by effort, unusual movements or attempt at control. They were not present during sleep or repose, when the activity responsible for them was manifested by twitching, choreiform or localized convulsive movements. Myotactic irritability was usually present and sometimes marked, in one patient with pronounced muscular hyperirritability to mechanical stimulation Chvostek's sign was elicitable at a time when the blood calcium level was normal. Symptoms referable to the respiratory or the urinary system are not usual at that stage.

A subnormal temperature is a customary observation, the morning temperature is at times as low as 96 F, and the temperature remains subnormal throughout the day. On the other hand, normal temperatures or even 0.1 to 1 degree of fever have been noted in patients with pronounced mental excitement, and one patient exhibited a sudden elevation of temperature to 106 F at a time when he appeared to be moribund. Some loss of weight is usual, beginning early it may persist for the entire course of the illness and result in losses as great as 25 pounds (11 Kg). The average loss of weight in the series studied was 9.3 pounds (4 Kg).

from an average weight of 157 pounds (71 Kg). Early in the disease and in the milder cases the blood changes are not significant. In table 2 the occurrence or nonoccurrence of the foregoing symptoms is noted. The symptoms noted are interpretations of the descriptions given by patients, not responses to leading questions, consequently the regular occurrence of several lends them considerable diagnostic importance. As far as time of appearance is concerned, it is generally true that the symptoms that appear most frequently make their appearance earliest and are the most severe and persistent.

When the exposure has been slight and brief, an exposed person exhibiting the aforementioned symptoms may have a recession of symptoms after a few days and may make a complete recovery in from two to three weeks. In most cases insomnia, dreams and muscular weakness are the most persistent symptoms and the progress of the case and recovery can be gaged by their course. If a marked depression in blood pressure occurs during the course of the disease, it will usually persist, as well as the symptoms previously

TABLE 2—Symptoms According to the Reports of Seventy-Eight Patients

mentioned. Kehoe,⁴ in his study of cases from Dayton, Ohio, many of which are included in this study, found that even in his moderately severe cases all symptoms had disappeared in from six to ten weeks.

In the more severe and acute cases following greater exposure the symptoms are present in greater number and may increase steadily in intensity. This is particularly true in the case of symptoms attributable to injury of the central nervous system, so that in the well developed severe case the mental manifestations dominate the clinical picture, completely overshadowing the changes in other systems. An exception is the occasional case in which the most marked changes are exhibited in the neuromuscular and circulatory systems. These will be described later. In the usual case several types of symptom complex can be distinguished: the delirious, manic, confused and schizophrenic. This division is essentially arbitrary and not fixed for any stage of the disease or for any individual patient, in fact, in any case there may be a fluctuation between periods of confusion and maniacal excitement or, after an episode of excitement, a period of schizophrenia may be noted accompanied with active hallucinations and delusions. In general, however, a given patient will manifest a type of mental response characteristic for

him, and not related to the severity of his illness or its stage, but apparently dependent on his mental background.

The delirious type of response does not differ markedly from other toxic deliriums. The patient is greatly depressed physically and is obviously sick, tremor is marked and the mood is one of fear or apprehension, though to a lesser degree than is usual in cases of delirium tremens. The patient seems to be completely dissociated from his surroundings, his attention is poor and his response to questions is often irrelevant or erratic, influenced considerably by the amnesia for recent events, which is uniform. Terrifying dreamlike experiences are carried over, hallucinations are common though less consistently so than in cases of alcoholic delirium. Misidentification of persons and places is usual and disorientation is frequently complete. Episodes of acute terror may lead the patient to attempt escape, every patient must at all times be restrained and under constant supervision to keep him from leaping from a window. Despite the great mental excitation and constant exaggerated muscular activity the pulse rate is relatively slow (less than 100), the temperature is characteristically normal or subnormal and sweating is profuse. In the greater proportion of cases there was delirium of the type just described, and it persisted for from a few hours to as long as four or five days responding well to treatment, however. Brief tonic convulsions may occur.

Patients exhibiting the manic type of response are not clearly differentiated from those having episodes of maniacal delirium. Symptoms of each type of response may be present and combined, indicating that the differentiation of type is a consequence only of relative degrees of emphasis on what are essentially mutual symptoms. However in two of the cases the mental manifestations were sufficiently characteristic to give the impression of maniacal excitement rather than delirium. Consciousness was somewhat clouded, less so than is usual in the delirious patients, the flight of ideas was marked almost to absolute incoherence, and transitory hallucinations were strikingly in evidence. Emotional exaltation was not noted, although it might be expected to be present in cases in which such marked psychomotor activity is seen, in fact, the tendency was toward depression with great restlessness. In both cases delirious mania developed with aggravation of all symptoms, and restraint was required. The somatic symptoms were in both cases similar to those previously described.

A state of confusion may precede, follow or intervene between attacks of mania or delirium. These patients will show little evidence of psychic irritability other than insomnia, restlessness and disturbed sleep. Motor unrest, muscular twitchings and exaggerated responses may be noted in this group as in the cases just described, and occasional hallucinations and delusional interpretations are seen. The patient for the most part is apathetic or depressed and is unconscious of or indifferent to his environment. A certain degree of perplexity is usually seen, especially in reference to the immediate environment and to orientation. Lucid intervals of from a few minutes to several hours may intervene, with improvement in orientation and insight, the amnesia for recent events not being improved greatly, however. A marked sensitivity to light was observed in one case. Prior to the onset of developing delirium or mania, there is a gradual increase in the

evidences of cerebral irritation. The expression becomes more anxious, restlessness increases, insomnia is intolerable and motor unrest is increased. These symptoms usually increase gradually over a period of from three to eight hours before the acute delirium supervenes, giving opportunity for intensive treatment in an attempt to abort the impending symptoms.

The schizophrenic type of response is by far the most confusing, particularly so in that in the two cases in which it appeared there was a history of behavior tending to indicate the likelihood of the occurrence of such a phenomenon without the supervention of the accident of tetra-ethyl lead intoxication. The mode of onset, initial behavior and general symptomatology did not differ in any essential from those of the other patients up to the time of the development of acute mental symptoms; there was a gradual increase in intensity of typical general symptoms over a period of from one to two weeks culminating in fairly acute psychic disturbance. The initial symptoms in both cases simulated the episodes of catatonic excitement seen in cases of dementia praecox, psychomotor activity was

counterpart does not develop. On the other hand the muscular weakness and ease of fatigue are pronounced and muscular pains and cramps are severe. No paralysis, anesthesia or other localized evidences of peripheral neuritis are to be seen, but the general muscle tone may be so lowered and fatigue so easily induced that work is impossible. A five minute walk may be sufficient to produce marked weakness in the legs requiring a correspondingly long period of rest. Finer movements are not interfered with and there is no true ataxia, but the rapid fatigue and muscle weakness may produce a type of poorly coordinated activity that simulates atactic movements. The tightly flexed biceps are doughy and yield to pressure, and there is moderate generalized tenderness of all muscles. The pulse rate is very slow and the temperature is definitely subnormal. The blood pressure is lowered to a point well below the average for other types. The tendon reflexes are hyperactive, no abnormal responses are noted and the sensorium is not affected.

In cases in which violent cerebral manifestations appear these may be terminated after a few hours or

TABLE 3—*Excretion of Lead in Fourteen Cases*

Case	Exposure	Type of Case	Interval Between Exposure and Collection of Samples	Milligrams of Lead per Liter of Urine	Milligrams of Lead per 100 Grams of Feces	Stippled Cells per 50 Fields	Recovery Completed After
C. A.	Accidental ingestion	Severe with three periods of mania, one convulsion	6 days	1.60	7.92	0	8 weeks
F. R.	Manufacture	Definite mild delirium	3 days	0.93	8.42		2 weeks

M. W.	Tank cleaning	Mild intoxication	5 days	0.19	1.68	0	1 week

increased, and the patients were impulsive, excessively talkative, noisy and destructive. There was complete sleeplessness and a marked lack of coherence with prominent hallucinations and delusions, the latter being fairly well formulated and organized. One patient was greatly depressed and fearsome with systematized self-accusatory, quasireligious delusions. His hallucinations and delusions were fairly well related to occurrences during the time of his youth. In the other patient periods of delirious excitement alternated with definite symptomatic paranoid states accompanied by delusions of persecution and auditory hallucinations. Both patients maintained psychomotor activity and were strikingly manneristic. Coarse tremors were generalized. The facies was empty and dull. Orientation and judgment were poor. Insight was lacking. The emotional poverty and inadequate emotional response were striking. The somatic symptoms were similar to those seen in other types.

In a type of case occasionally seen—two such cases were studied—the mental symptoms are not prominent, though evidences of cerebral irritation can be elicited, the predominant symptoms are neuromuscular or neuro-circulatory. Anorexia, restlessness, insomnia and dreams are present, in fact, insomnia may be so severe as to prevent sleep for days, yet the delirium or its

days and a subsequent decline in all other symptoms may occur, to be followed by an uninterrupted convalescence. The delirium may however decline in intensity to a level at which the patient requires no restraint and then, after a period of as long as two or three days, recur. It is to be noted in these cases that in the intervals between periods of delirium the improvement in the remaining symptoms, particularly the somatic symptoms, does not progress, instead the condition remains more or less stationary, with a decline prior to the recrudescence.

Clinical laboratory observations are of little diagnostic significance. A marked drop in the hemoglobin value, which occurred in one case immediately following exposure, was not maintained. The urine is in nearly all instances acid to methyl red, in addition, particularly during periods of delirium, it may contain albumin and sugar. Occasional casts may be seen. Records of but six spinal fluid examinations are available. None were remarkable in an uncomplicated case. During the delirium the pressure was slightly increased but in two patients who were allowed to become dehydrated the pressure was subnormal. All counts and the globulin and chloride values were within normal limits. The sugar content of the spinal fluid was in two cases over 80. The gold curves in two cases were negative.

Chemical examination of the urine, feces and blood yields evidence of a definite character in relation to the patient's exposure to lead. The rapid rate of absorption and excretion of many of the organic compounds of lead results in the appearance in the urine during the period immediately following exposure of quantities of lead materially greater than those seen at a corresponding period in plumbism from other lead compounds, and completely at variance in amount from the quantities normally excreted. Table 3 gives the results in fourteen cases of examination of the urine and feces in relation to the period following exposure.

DIAGNOSIS

The diagnosis rests on the history of a significant exposure to organic compounds of lead, the observance of symptoms and physical observations consistent with those just described, and the finding of amounts of lead in the urine and feces of the order of magnitude of those found in the cases described. (Only in certain cases have the chemical analyses of the blood and spinal fluid revealed amounts of lead that could be considered significant, but the limits of normal variation are so poorly defined at present as to make questionable any interpretations based on these results.) The interpretation of a significant exposure must depend on a knowledge of circumstances under which such exposure occurred and on the knowledge that similar exposures have been significant and have led to poisoning in other instances. A variety of conditions may offer difficulties in differentiation. Delirium tremens and toxic delirium from other causes, such as drugs, bromides, carbon monoxide and mercury, offer the greatest problem, particularly if they chance to occur in a worker who has had in addition a potential exposure to tetra-ethyl lead. Mental symptoms due to acute uremia, pellagra, the delirium of acute infectious diseases as well as those psychoses with delirium associated with organic brain disease, such as epidemic (lethargic) encephalitis may be confusing to the examiner. Low grade infections associated with chronic ill health are often accompanied with such symptoms as hypopnea, disturbance of sleep, anorexia and weakness. The differentiation of such a case from incipient cases of intoxication can be accomplished when an adequate history is given. In some instances in which a history cannot be obtained the diagnosis must rest entirely on the distribution and nature of the chemical observations. Most patients, however, will not present any great problem in diagnosis, particularly if one keeps in mind the limited groups of persons who may be exposed, the direct relation between exposure and illness, the continuity of symptoms and the essentially general nature of the cerebral manifestations. The coincidence of tetra-ethyl lead intoxication and other diseases has been seen. One patient having a history suggesting the possibility of developing dementia paralytica and for whom the spinal fluid showed a typical gold curve and the serologic tests were positive for syphilis had superimposed a mild intoxication. All symptoms disappeared during convalescence, antisyphilitic therapy having been instituted as soon as the acute symptoms of intoxication began to subside.

COMPLICATIONS AND SEQUELAE

In mild and moderately severe cases in which there were brief periods of delirium no complications developed. As a consequence of circulatory weakness and exhaustion in severe or fulminating cases a variety of complications may conceivably develop such as acute

cardiac dilatation, cerebral edema, pulmonary edema or similar lesions associated with terminal states. No complications occurred in the present series, however.

Sequelae have not been seen. Convalescence may be protracted with symptoms persisting as long as from eight to ten weeks, but no residual symptoms or evidences of damage have been observed. A group of fourteen patients not included in this series have been under medical observation at monthly intervals continuously since the time of intoxication in 1925 and have not given any evidence of subnormality, physical alteration or increased susceptibility to intoxication. They have been continuously at work in the manufacturing operation, the majority of them having been in supervisory positions during the past two years where the exposure is often greater than that experienced by day workmen. Such evidence plus the absence of focal brain lesions at necropsy, indicates the reversible nature of the injury from tetra-ethyl lead and reduces the likelihood of damage from cumulative subclinical exposures.

TREATMENT

Prophylaxis consists in having the manufacture handling and blending of these compounds carried out in closed systems. Where this is not feasible, as in laboratory operations, the use of impervious gloves and respirators is indicated. The results obtained through the exercise of precautionary measures in the manufacturing processes have been given in a recent article by Kehoe.¹⁶

In mild cases little symptomatic treatment is required. Termination of the exposure, light outdoor exercise and a normal diet with a high intake of water are all that is usually necessary. Small doses of pentobarbital sodium or paraldehyde will usually control the insomnia. The bowels should be kept open, preferably by the use of saline cathartics. In severe cases more vigorous treatment is indicated. Maintenance of an adequate intake of fluid is a major problem in delirious patients, the voluntary intake in such cases being nil and the losses excessive. The intravenous administration of from 500 to 1,000 cc of physiologic solution of sodium chloride or a 5 per cent solution of dextrose in physiologic solution of sodium chloride as often as every eight hours may be necessary, and the response is usually favorable. The delirium may be controlled by the intravenous administration of from 2 to 4 Gm of magnesium sulphate in 2 per cent solution accompanied by doses of pentobarbital sodium up to 15 grains (1 Gm) daily by mouth. Calcium lactate and viosterol may be given to maintain an adequate intake of calcium. Saturated solution of magnesium sulphate given in from 4 to 6 ounce (120 to 180 cc) doses as a retention enema had a noticeably quieting effect in three cases in which the patients were able to retain it. The treatment of the acute stage was essentially symptomatic and supportive. Adequate calcium and phosphorus were assured and no attempts were made to facilitate the storage or to expedite the excretion of lead. Calcium chloride and gluconate, as well as sodium thiosulphate have been administered in the usual doses intravenously without influencing the course of the disease. Light ether anesthesia was induced in two patients without apparent subsequent harm.

During convalescence the problem of deleading arises. It is generally recognized that acute infections, metabolic

¹⁶ Kehoe, R. A. Thammann, Frederick and Cholak, Jacob. Lead Absorption and Excretion in Certain Lead Trades. *J. Indust. Hyg.* 15: 306 (Sept.) 1933.

upsets or alteration in the calcium and the phosphorus metabolism¹⁷ may profoundly affect the storage, mobilization and excretion of lead, and the dangers of attempting to expedite the excretion of lead are well known. Too little information is available, however, to justify the use of deleading procedures as a routine measure in diagnostic or therapeutic practice. Moreover it has been shown¹⁸ that abnormal amounts of lead are excreted naturally over a period of from twelve to eighteen months. As none of the patients in the present series manifested sequelae or delayed recurrences attempts to promote excretion were not made.

Clinical Notes, Suggestions and New Instruments

TETANUS TETANUS ANTITOXIN OR PHENO- BARBITAL DEAFNESS

EMIL ANDERG, M.D. AND ROBERT S. HEWITT, M.D. DETROIT

C. S., a youth, aged 17 years, a patient of Dr. Glenn Stockwell, entered Harper Hospital Oct. 29, 1934. The patient had run a thorn in his right heel October 21, while hunting. For several days there had been a small localized inflammatory area at the site of the wound. About thirty-six hours before admission there was noticed some difficulty in opening the jaws. Physical examination revealed that the neck was somewhat rigid. The lower jaw was drawn back slightly and the patient was unable to open it. The abdominal muscles were very rigid, and all reflexes were extremely hyperactive. There was a definite ankle and patellar clonus. Until November 3 heavy doses of tetanus antitoxin were given. November 3 at 3 a. m. the patient became very cyanotic. Respirations were of Cheyne-Stokes type. The temperature was 103 F. November 5 there was severe urticaria over the entire body. November 6 the condition was not improved. The pulse was very rapid. The nurses were unable to count the number. Edema of the face and hands was very severe. The patient was rational at times. Apparently total deafness was first noted November 9. November 16 the patient complained of noises in both ears. The sounds were described such as those of a trolley car or of a meat grinder. The patient heard no sounds when a Bárány noise apparatus was put to either ear. The fundi were normal. There were no vestibular disturbances. The patient had continually talked in a very loud voice since the onset of the deafness. November 21 the hearing test was repeated. The patient stated that the noise was louder when a tuning fork was applied over the mastoid area than when it was applied over the forehead.

From October 29 to November 3 the patient received 120,000 units of tetanus antitoxin intraspinally, intravenously and intramuscularly in doses of 20,000 units. October 29 phenobarbital, one-half grain (0.03 Gm.), was given every three hours. October 30 phenobarbital, 1 grain (0.065 Gm.), was given every three hours when the patient was awake. November 1 the medication was the same. November 9 it was discontinued. November 3, one ampule of coramine was given. November 7, one ampule of coramine was given. November 1 and 4, sodium amytal, 3 grains (0.2 Gm.), was given. Dextrose was administered. Saline solution was administered repeatedly. November 9 a retention enema was given (chloral hydrate, 20 grains, or 13 Gm. and sodium bromide 30 grains or 2 Gm.). November 5, epinephrine was given for itching 3 minims (0.2 cc.) when needed.

The patient came to the office March 8, 1935. Examination revealed no particular abnormality of the drum membranes. He appeared to be totally deaf. The Edelmänn a-1 fork, the

Dench loaded low fork and the 4,096 fork were not heard in either ear. May 21, tuning forks at 96, 128, 256, 512, 1,024, 2,048 and 4,096 vibrations were not heard in either ear, but the "toy clicker" was heard in the left ear in a distance of 7½ inches (19 cm.) and in the right ear in a distance of about 1 inch (2.5 cm.), while the noise apparatus sounded in the left ear. Politzer's audiometer was not heard when applied to either ear. We found only collateral reference by Dr. O. Benesi of Vienna in his contribution "Neuritis toxica nervi octavi" in the Handbook of Neurology of the Ear, page 814. He mentions under "bacterial toxins" "We are oriented concerning the influence of bacterial toxins by virtue of animal experimentation. Naturally, there are scarcely any clinical observations." C. Hirsch, for instance, reports an isolated neuritis vestibularis after immunization for typhoid. Moos has described ecchymoses in the acoustic nerve in diphtheria. Our patient received numerous doses of phenobarbital. Benesi (p. 799) reports the history of a patient who had taken large doses of phenobarbital (from 4 to 5 Gm.) and became totally deaf on the right side while he could hear the whispered voice on the left side at a distance of 3 meters. He also suffered from vertigo and fell to the right backward.

CONCLUSION

Our patient suffers from almost total deafness in consequence of either tetanus, tetanus antitoxin or, possibly, phenobarbital.

Further observations in other patients may establish a more definite etiology.

PAROXYSMAL HYPERHIDROSIS IN A DIABETIC PATIENT WITH REMISSION UNDER AMYTAL THERAPY

EDGAR HULL, M.D. AND PAUL B. CAMERON, M.D.
NEW ORLEANS

M. B., a Negro woman, aged 40, first came under our observation in July 1934. She was ushered rather dramatically into the diabetic clinic, staggering on the arm of the attendant. She was gasping for breath and unable to talk. Her clothing was drenched with sweat, huge beads poured from her face and neck, and from her dependent fingers drops fell with regular frequency, forming a pool on the floor. She had been sitting quietly on the bench awaiting her turn to be seen when this attack occurred. Since we believed this to be an insulin reaction, she was immediately given orange juice, and in a few minutes she was herself again, except for the drenched clothing. We were amazed to learn that she had taken no insulin and to find that these attacks had recurred at intervals of approximately two hours for the past nine years, day and night. The nocturnal attacks would awaken the patient from a sound sleep, and they necessitated changing the bedclothing.

Her past history revealed that she had had a normal childhood and adolescence. She married in 1910 and a normal child was born the same year, there had been no miscarriages. In 1914 she had what was apparently hydrarthrosis of the knees, with spontaneous subsidence, and later that year jaundice for a few weeks. In 1915 a pelvic operation was performed ostensibly a unilateral salpingo-oophorectomy, and in 1921 it was necessary to repair a hernia at the site of the operation. In 1925 the sweats began, occurring every two hours, but in a mild form. Since then the severity had increased. In 1926 a physician, consulted for the relief of pruritus vulvae, found glycosuria and instituted a regimen. This was apparently not followed as in 1928 she was brought to this hospital in diabetic coma. An irritative vulvitis found at this time was incorrectly diagnosed syphilitic condyloma, as it disappeared with control of the diabetes. Casual mention was made in this and subsequent histories of the paroxysmal sweats, but no investigation was made.

The family history was without significance.

After close observation in the hospital for several weeks, all her statements were verified. The sweats recurred with

17 Aub, J. C., Fairhall, L. T., Minot, A. S. and Reznikoff, Paul. Lead Poisoning in Medicine. Baltimore, Williams & Wilkins Co. 1926, vol. 7.
18 Kehoe, R. A., Thamann, Frederick and Cholak, Jacob. Lead Absorption and Excretion in Relation to the Diagnosis of Lead Poisoning. J. Indust. Hyg. 15: 320 (Sept.) 1933.

From the Departments of Medicine, Louisiana State University Medical Center and the State Charity Hospital of Louisiana.

regularity every ninety to 120 minutes, throughout the twenty-four hours. Emotional upsets appeared to shorten the inter-sweating period. Reading for more than a few minutes caused an interval of, roughly, ninety minutes but the disturbance at visiting time in the ward had no effect. A definite premonition or aura preceded the actual diaphoresis by two or three minutes, and the height of sweating was marked by a feeling of faintness, thoracic oppression, palpitation and dyspnea, and disappeared on cessation of the attack, leaving weakness and lethargy for ten or fifteen minutes longer. Actual sweating lasted about ten minutes on the average.

Weighing the patient before and after sweats, as well as weighing bedclothing before and after, indicated a weight loss of from 180 to 300 Gm during the paroxysm.

The blood pressure varied from 90 systolic, 70 diastolic and thereabouts without change during the attacks.

The temperature taken over several hours at ten minute intervals, during which more than one sweat occurred, showed no fluctuation at all. The patient's temperature varied from 97 to 98 F and did not vary during the cycle.

The basal metabolism readings have been 0 and —3 per cent. A roentgenogram of the skull shows a slight erosion of the sella, which has remained constant for the past year. The fundi and visual fields are normal.

Analysis of the sweat showed not more than 3 mg of dextrose per hundred cubic centimeters, 351 mg of chlorides, 387 mg of ammonia and 21.5 mg of urea nitrogen.

Results of the examination of the blood are given in the accompanying table.

Blood Analysis

Blood	Nonprotein Nitrogen	Urea	Sugar	Chlorides
30 minutes before sweat	37	16.8	200	468
At beginning	38	17.4	220	455
At height	39	18.2	246	436
At end	38	17.2	240	447
30 minutes after sweat	35	17.2	240	454
One hour after			230	462

It is seen that all constituents of the blood tested remained practically unchanged with the exception of the sugar. The patient had a high threshold, and several times glycosuria was noted immediately following the paroxysm. At times the sugar has risen more than 60 points.

The diabetes is becoming more and more severe. On the admissions in 1928 and 1930 it was possible to keep the patient sugar free and with a normal or nearly normal blood sugar, with 20 units daily on a low carbohydrate diet. At the present time, on a diet of 150 Gm of carbohydrate, 60 Gm of protein and 80 Gm of fat, she maintains her weight and shows traces of sugar on 70 units daily, but shows persistently high sugar, from 200 to 240 mg.

All manner of drugs were tried, with little or no effect. At the suggestion of Dr. Wilder of the Mayo Clinic, who had seen a similar case at Rochester, Minn.,¹ sodium amytal was given with startling results. This drug in doses of from 3 to 6 grains (0.2 to 0.4 Gm) nightly, enabled her to sleep through the night, and although sweats took place she was unaware of them. She has been discharged from the hospital and observed carefully at frequent intervals. At the present time she takes 3 grains morning and night. Sweating occurs, but the amount of sweat has diminished markedly and is scarcely enough to dampen a handkerchief. Whereas formerly she had to sit down during an attack and was rendered gasping and speechless, now she is able to carry on a conversation and vows she experiences no subjective symptoms. The attacks are becoming less and less severe, and the patient feels confident of ultimate recovery. Cessation of the drug causes the attacks to recur with their former severity. Curiously enough the patient states that she does not feel sleepy even when taking from 12 to 15 grains (0.8 to 1 Gm) daily.

¹ Hines, E. A. and Bannick, E. G. Intermittent Hypothermia with Disabling Hyperhidrosis. Proc. Staff Meet. Mayo Clin. 8:705 (Nov. 21) 1934.

SUMMARY

We have no explanation to offer for this case of paroxysmal hyperhidrosis in a diabetic patient. The first diagnosis of hysteria seems to be disproved, in spite of the strong emotional influence on frequency and severity, as shown by reading or by the appearance of off-schedule attacks during staff ward rounds or amphitheater demonstration of the patient. Other conditions considered have been so-called epileptic equivalents: low-grade encephalitis, syphilis, because of the somewhat suggestive past history, and intracranial tumor, because of the eroded sella. None of these seem disproved, and very little definite evidence has been brought out in favor of them. Many of the objective and subjective phenomena occur with over dosage of epinephrine, and a disturbance of the sugar metabolism during the attacks favors the hypothesis of derangement of the epinephrine balance, the exact nature of which we are not in a position to state.

We have been able to find one similar case,¹ with remission under amytal. Our patient does not show the subnormal temperature described in the Rochester case.

A MINIATURE DARK ROOM DEVICE FOR OPHTHALMOSCOPES

CHARLES POSNER, M.D., PASADENA, CALIF.

Every physician who makes a practice of including a retinal study in the general physical examination of his patient has probably, like myself, been troubled by the necessity of converting the patient's room into a dark room for a satisfactory study of the eyegrounds. In order to overcome this difficulty it occurred to me that I could convert my ophthalmoscope into a miniature dark room. This was accomplished, as shown in the illustration, by attaching an aluminum eyecup to both sides of the revolving lens system of the instrument. The inside of

A side view B front view and C rear view of miniature dark room.

the cups was painted with a dull finish black paint, which absorbs the side reflections from the wheat gram bulb, so that there is less reflected light to dazzle the eye of both the patient and the examiner. Furthermore, extraneous light is cut off when the eyecups are applied to the eyes of both the examiner and the patient. In order to reduce further side emanations of light from the wheat bulb, I found it a good plan also to coat the sides of the bulb lens with dull finish black paint.

The device described was arranged as illustrated on my Weisch Allen ophthalmoscope, which is of the direct illuminating type. With a little practice one can easily adjust oneself to the new arrangement. I hope that this idea will be of benefit to those physicians who wish to improve their eye examinations in the patient's home.

TREATMENT OF DIABETIC COMA

CLINICAL LECTURE AT ATLANTIC CITY SESSION

HENRY J. JOHN, M.D.
CLEVELAND

Diabetic coma presents a major medical emergency. Like any major emergency it must be dealt with promptly, efficiently and adequately. These are the three cardinal axioms if life is to be saved.

The first clinical description of diabetic coma was given by Stosch in 1828, referred to by Warburg.¹ A German, von Dusch, and a Scotsman named Marsh described it again in 1854.

Coma is not merely the result of intoxication with ketone bodies, but other thus far unknown acids are

Such then is the picture which the patient presents. Fortunately it is a picture that is easily recognizable but one must be on guard concerning the diagnosis. The points that are helpful in establishing the diagnosis are as follows:

1. A history of diabetes, the type of onset of coma and the presence of infection. Coma, however, may be the first clue that the patient is diabetic.
2. Glycosuria, ketonuria and an odor of acetone on the breath.
3. High blood sugar and low carbon dioxide determinations.

These three points practically cover the field. A diabetic patient usually drifts into coma slowly over a period of two or three days, although there may be exceptions, especially if infection is present. As acidosis develops it is easy for him to forget about the necessity of taking insulin, since his mental faculties are dulled and his family often know little or nothing about his condition.

TABLE 1—Differential Diagnosis of Coma

	Eyes	Breathing	Glyco- suria	Blood Urea Content	Blood Sugar Content	Onset	Head ache	Acetone	Carbo- dioxide Combining Power	Comment
Diabetic coma	Soft eyeballs	Kussmaul	Marked	Normal or high	Normal or high	Rapid or gradual	Present	Present to breath urine and blood	Low	Low blood pressure vomiting often present
Nephritic coma (uremia)	Pupils usually dilated, albumi- nuria, retinitis edema	Stertorous	Usually present but may be absent	High	Normal or slight rise	Gradual	Present	Present to breath urine and blood	Normal	Pressure on lumbar puncture but clear fluid, high blood pressure
Cerebral hemor- rhage	Pupils dilated and unequal conjugate deviation	Stertorous and slow spitting relaxed and foam-covered lips	Usually present but may be absent	Normal	Normal or slight rise	Rapid	Present		Normal	Unequal resistance of limbs on lifting high blood pressure
Fracture of skull	Early dilatation of pupils		May be present	Normal	Normal or slight rise	Rapid	Present		Normal	Roentgen examination of skull will establish diagnosis
Brain tumor	Choked disk changes in visual fields	Normal	None	Normal	Normal or slight rise	Slow	Persistent or paroxys- mal often violent		Normal	Apathy, projectile vomiting at its maximum in a m
Meningitis	Pupillary changes dilated or unequal pupils	Rapid	Present	Normal	Normal or slight rise	Sudden	Present		Normal	Koenig sign, lumbar puncture, leukocy- tosis, fever
Insulin reaction	No changes in eyes	Normal	Absent after second catheteri- zation	Normal	Low though a high figure may be en- countered	Sudden	None	May be present	Normal	

liberated in the blood and the urine in coma. Their identification will eventually throw a great deal of light on the problem. Clinical observations and, as Allen and Wishart have shown in their extensive studies on dogs, experimental evidence indicate that this fatal disorder is due rather to some metabolic derangement of which the chemical manifestations are only a superficial and variable expression.

The picture of a patient in coma is that of a very sick person which even a layman can appreciate. There is unconsciousness, labored breathing, a dry, parched mouth and a tongue covered with dry, encrusting debris, which is often discolored. One appreciates that the body is markedly dehydrated. There may or may not be vomiting. The odor of acetone can be detected on the breath, the cheeks are usually flushed, although pallor in the early stage is often present. The pulse rate is rapid and the blood pressure low.

One should bear the following conditions in mind in making a differential diagnosis: hypoglycemia, acute infections in nondiabetic children, meningitis, uremia, brain tumor, thrombosis and embolism (table 1).

If one tries to visualize the physiologic upset that accompanies a state of coma, the treatment is easy and obvious. Three primary factors must be dealt with (table 2):

1. The diabetic complex of hyperglycemia, an excess of ketone bodies circulating in the blood stream and damaging the organism, and a low alkali reserve. The administration of insulin rectifies these three abnormalities.

2. The tissues are depleted of water because of the increased excretion of water due to the high blood sugar content. The body tries, so to speak, to wash out the excess sugar from its tissues, and water unfortunately goes with the sugar, leaving the body in a sad state of dehydration. This in turn means a reduced blood volume and low blood pressure. The blood is concentrated and shows a high red cell count and high hemoglobin value. The blood urea content is high prob-

Read before the General Scientific Meeting of the Eighty-Sixth Annual Session of the American Medical Association, Atlantic City, N. J., June 11, 1935.
1. Warburg, E. Diabetic Coma with Uremia. *Hospitalist* 67:841, 864, 1924.

ably for the same reason and because of the deranged metabolism and the blood chloride value is low. It is obvious what will rectify this part of the picture—an abundance of fluid and salt given by hypodermoclysis or intravenously.

3 The tissues are unable to utilize carbohydrates adequately because of a lack of insulin, a lack of water and poisoning by ketones. All three of these conditions

TABLE 2—*Diabetic Coma*

1 Diabetic complex	} Rectified by insulin
Hyperglycemia	
Excess of ketone bodies	
Low alkali reserve	} Rectified by abundance of fluids hypodermoclysis or intravenously
2 Dehydration complex	
Tissues depleted of water	
Low blood volume and pressure	} Rectified by insulin fluids and alkalis in small quantities
Concentrated blood	
(a) High hemoglobin value and erythrocyte count	
(b) High blood urea value	}
(c) Low blood chloride value	
3 Tissue starvation (all these factors exhaust the energy reserve)	
Inability to utilize carbohydrates due to	}
(a) Lack of water in tissues	
(b) Lack of insulin	
(c) Poisoning by ketosis	

exhaust the reserves of energy. Insulin fluids and alkalis administered in small quantities will rectify these abnormalities.

The causes of coma most frequently encountered are inadequate treatment, omission of insulin, infection, neglected diet or dietary indiscretion, hyperthyroidism, a simple operation and nervous shock.

ROUTINE TREATMENT OF COMA

The rational treatment of diabetic coma depends on two main aids (1) insulin and (2) fluids. To these can be added other accessory items—dextrose, alkalis, fruit juices and general care.

How rapidly should insulin be administered? No definite rule can be established in this regard, as each patient presents a unique problem. While one patient may require as little as 25 units of insulin, another may need as much as 1,200 units during the first twenty-four hours. There is more danger of using too little than too much insulin. I usually start with 40 or 50 units given intravenously and follow this with 20 units every half hour until the blood sugar level reaches about 250 mg per hundred cubic centimeters of blood. From then on, insulin is given every hour or two in the same dosage. If dextrose or physiologic solution of sodium chloride is given, the insulin is incorporated in the solution.

As I look over my charts on cases of coma I see that such a rapid and continuous dosage of insulin brings results in from six to ten hours. A slower administration of insulin with intervening periods of several hours takes longer to bring the patient out of coma, and I think that it weakens him. Chart 1 gives data recorded during a period of coma in a girl aged 2 years. The initial blood sugar value was 500 mg and the carbon dioxide-combining power 13 cc per hundred cubic centimeters. I gave at first but 5 units of insulin every half hour, as this was my first case of coma in an infant, increasing this later to 10 units every half hour. A total dosage of 125 units of insulin was given before the child came out of coma, which lasted for nine hours. In contrast to this is shown chart 2, which represents the data in a case of coma in a woman 45 years old. The initial blood sugar value

was 894 mg and the carbon dioxide-combining power was 109 cc. This patient received 650 units of insulin in the course of twelve hours together with three doses of a 10 per cent solution of dextrose intravenously before the coma was under control.

The total amount of insulin administered to the grown person seems large in contrast, but if the dosage per hour per pound of body weight in the child and in the adult is computed it is found to be 0.5 unit in the child and 0.3 unit in the adult. Such a comparison, however, will not hold in all cases, for an obese person would naturally show a low ratio of insulin with a dosage of 650 units.

The treatment of diabetic coma is simple when one has free access to a laboratory and can ascertain the patient's condition from hour to hour. One should be able to work fast and with precision. But how about the care of the patient in coma who is at home where none of these facilities exist? That often is the case. I can best answer this question by citing a parallel problem. What should the physician do out in the country if he is confronted with an acute case of appendicitis and has insufficient instruments with him? Should he perform an emergency operation or put an icebag on the patient's abdomen and take him to a hospital where adequate facilities are available? There is no question about the answer, for medical men have been trained for surgical emergencies and they are being trained for the emergency of diabetic coma. The comatose patient

Of the fifty-four patients 81.5 per cent showed a fall in the blood sugar content, 3.7 per cent showed no change, 14.8 per cent showed a rise. The average fall in the blood sugar content was 29 mg per hour; the average rise was 19 mg per hour.

should be given from 20 to 40 units of insulin hypodermically and sent to a hospital where he can obtain adequate help. The preliminary dose of insulin is to the patient in coma what the icebag is to the patient with acute appendicitis—it slows up the disease process and gives the patient a chance.

The importance of fluids is equal to that of insulin. A body that is dehydrated must have the 10 to 20 per cent loss of water replenished if the individual cells are to work efficiently. A motor will not operate on

gasoline alone oil and water are also essential. Fluids are supplied to the diabetic patient by means of physiologic solution of sodium chloride given by hypodermoclysis, intravenously and later orally. A good way to supply a portion of the fluids is at the end of gastric lavage, after the washings come clear, to leave from 300 to 400 cc of water in the stomach. I use slightly alkalinized water quite warm, for this purpose. The question of the use of alkalis has its supporters² as

well as its antagonists³. I think that the main argument is against the excessive use of alkalis as it is apt to upset the stomach and also it often brings on edema. Murdfield⁴ even reported a case of rupture of the stomach following the use of sodium bicarbonate.

Another way in which a patient can receive a portion of the fluids is by the intravenous administration of a 10 per cent solution of dextrose made up in physiologic solution of sodium chloride. I use this frequently, though not always, and my impression has always

been that these patients have improved faster. One can readily see that a patient in coma, who has gone through acidosis into coma, has not had any food for from one to three days. He needs food and liquids. The liver is glycogen poor or glycogen free and it needs replenishment. It is true that the blood sugar value is high and therefore there should be no need to crowd in more sugar. However, the height of the blood sugar level is but one link in the entire chain. If the patient is given 250 cc of a 10 per cent solution of dextrose he receives 25 Gm of dextrose. Normally 12 units of insulin should take care of this, but I give from 30 to 50 units of insulin in this solution. This means that a hotter carbohydrate flame is created which helps to consume

the ketones that are damaging the body, and the increased volume of liquid helps to wash out the rest through the kidneys. A normal animal can rebuild its glycogen reserves from added dextrose and burn the fatty acids, and a patient in coma also will if given dextrose, water and insulin. That there is no appreciable rise in the blood sugar content following the administration of dextrose (in fact most of the time there is an appreciable fall in the blood sugar value), I⁵ have shown in previous publications and I am reproducing the figures here in table 3. There has always been a fear of causing a rise in the blood sugar level in the diabetic patient, but in reality a rise does not occur. I learned to appreciate the value of the intravenous administration of dextrose to nondiabetic patients during the war when I used it extensively in cases of pneumonia⁶ and other conditions, and when years later I was confronted with cases of diabetic coma I applied the same measures with equal success.

The use of intravenous injections of dextrose has many advocates⁷. As much as from 100 to 200 Gm of dextrose can be administered in this manner so that when it burns up it can create an antiketogenic action. In this manner the incomplete combustion of fatty acids is reduced to a minimum and the production of ketone is thus limited and the combustion of ketones already present in the blood and the tissues is aided. The answer which Petren² gave to this question of the intravenous administration of dextrose was that of thirty-eight patients in coma to whom he gave dextrose thirty-seven recovered.

If a patient has been vomiting he has lost a great amount of chlorides in this manner and the supply therefore needs replenishment. Physiologic solution of sodium chloride will take care of this either when given by hypodermoclysis or intravenously as dextrose in physiologic solution of sodium chloride. While the ketones can be eliminated by the use of dextrose, insulin and water, still a relative alkali-

losis is created, as indicated in chart 3, which was constructed after that of Hartmann and Darrow. From this it is clear that the administration of physiologic solution of sodium chloride is important in order to reestablish a normal physiologic equilibrium.

Having discussed the two main aids in the treatment of diabetic coma, insulin and fluids, which are of primary importance, I shall next consider the following accessory items, which are also of great importance:

- 1 Absolute rest with plenty of warmth to the body
- 2 Gastric lavage
- 3 Cleansing of the intestinal tract
- 4 Adequate nursing and medical care
- 5 Support of the circulation
- 6 Nourishment citrus fruits
- 7 Alkalis

The absolute rest is automatically taken care of because the patient is unconscious. The saving of energy to the body by the use of plenty of warmed blankets next to the body and hot water bottles so as to prevent any unnecessary dissipation of heat means much to the patient.

The clearing out of the stomach of undigested food is of importance, for food which the patient ate from

Chart 3—A schematic representation of diabetic ketosis and the changes after the administration of dextrose and insulin and after the administration of dextrose, insulin and physiologic solution of sodium chloride (reconstructed after Hartmann and Darrow).

twenty-four to forty-eight hours previously often lies undigested in the stomach. This must all be washed out until clear fluid returns from the lavage. It is well to use slightly alkalinized water, quite warm, for this purpose. When the fluid comes clear it is well to leave the last 300 to 600 cc of alkalinized fluid in the stomach. Also a dose of castor oil can be given through the tube into the stomach in order to ensure a complete evacuation of the bowel. If castor oil is used, one can well wait an hour or so before giving an enema. This makes it possible to administer dextrose by hypodermoclysis or intravenously without loss of time. If no cathartic has been used, then a saline enema is given as soon as possible.

Washing out of the stomach is an important procedure. I know of one death that occurred because this was overlooked. The patient was brought out of the coma chemically so that the blood sugar value and the carbon dioxide-combining power were normal, but suddenly she became cyanotic and the respirations ceased though the heart kept on beating. Artificial respiration was resorted to and breathing started but after a while ceased again. Artificial respiration was resumed and a Drinker respirometer used but to no avail, the patient died. This presented a problem as to what was the cause of death since the patient had been brought

out of coma chemically and death in coma presents a cardiac not a respiratory failure. Autopsy cleared up the problem. While the patient had been brought out of coma, the general weakness had still been marked. The stomach contents had been regurgitated and had trickled down the trachea and choked her. I am therefore emphasizing the point of gastric lavage, as one lesson should be enough to prevent similar accidents. It is better to perform a few unnecessary lavages and be on the safe side than to lose a patient because of their omission.

The importance of the nursing and the medical care is obvious. There is no other emergency in medicine which requires a closer supervision day and night until the patient is out of danger and for some time after that for a relapse may occur in a few hours if treatment is not sustained. To care for a patient in coma is not a matter of a few hours but a continuous day and night problem until the patient is safe. There is where laboratory data enable one to proceed with safety and assurance by eliminating all guesswork.

Circulatory stimulants are indicated. Caffeine sodium benzoate, from 6 to 9 grains (0.4 to 0.6 Gm.) at a time, may be incorporated into the solution of sodium chloride and dextrose given intravenously. However, it must be remembered that the restoration of the volume of blood through hypodermoclysis or the intravenous administration of dextrose with insulin is one of the best cardiac supports that can be given the diabetic patient in coma. Most of the time this is all the support that needs to be supplied. Clearing the circulation of the concentrated ketone bodies relieves the heart of an irritating and weakening factor and gives it a chance. One should bear in mind, however, that a patient who has just been brought out of coma to consciousness is like a patient who has just recovered from typhoid fever or pneumonia. The heart is weak and needs protection. I saw one patient years ago who came out of coma and seemed to be doing nicely, but the mere strain on a bed pan and being in an upright position brought on a fatality. One cannot be too careful of these patients and caution is necessary.

When the patient can take liquids by mouth, this helps to reduce or to eliminate the required amount of exogenous liquids. Citrus fruits are the best to use at the beginning, as they tend to bring about the swing toward the alkaline side and thus partly counteract the acidosis. Lemon and grapefruit juice are the best. I have found that when there is a tendency to nausea the patient does not tolerate orange juice well. It is apt to bring on vomiting and that weakens the patient. If orange juice is used at all, it should be well diluted with water. A weak lemonade or grapefruit-ade is preferable. This can soon be followed by a soft diet, starting with oatmeal gruel, milk toast and buttermilk.

The use of alkalis is much disputed. It has many adherents² and many opponents.³ The truth lies probably somewhere in the midground. Alkalis should be used sparingly and as such can do no harm and are often of help. The easiest way of furnishing alkalis is, as previously mentioned, through the gastric tube after lavage at the beginning of the treatment. This probably will suffice, but the carbon dioxide values will indicate any further need for this.

MORTALITY STATISTICS

The mortality in diabetic coma is still high. One needs but to glance over the world literature to be convinced of this. According to data given by sixteen

authors on 424 cases of coma the mortality was 19.2 per cent. This is a high average ratio and time will no doubt improve it. Mortality figures as given range from 0 to 55 per cent.

There is one way of bringing about a better result and that is by early treatment. Adequate treatment comes next in importance. However, adequate early treatment presents an entirely different picture from that of adequate treatment late in the condition, there will be two entirely different sets of figures no matter who takes care of the patients. The main effort should be made to lose no time in starting treatment. If one sees a patient in coma at his home or if one has a telephone call from the family physician and the diagnosis is reasonably certain, give or direct to be given 40 units of insulin immediately, before the patient is taken to the hospital thus saving the loss of at least an hour. If a patient must be brought from any distance, have 40 units given at first and then 20 units every half hour thereafter until he reaches the hospital. Many lives will be saved in this manner. I noticed that in the last review of my cases of coma Joslin classified some of these as cases of acidosis, since he differentiates coma from acidosis merely by the carbon dioxide values. The higher carbon dioxide values that I reported were obtained when the patient reached the hospital and after he had had the preliminary dose of insulin on the way. These were cases of coma and not mere acidosis. It is more important to start treatment at once and obtain the laboratory data later than the reverse. Laboratory data are to be used merely as a guide and all statistics must be interpreted with caution.

Death in coma is often due to vasomotor collapse, septicemia, uremia, aspiration of gastric contents into the trachea or terminal hyperpyrexia.

HYPOGLYCEMIA

Hypoglycemia as brought about by the excessive use of insulin is still dreaded by many physicians. The fear of hypoglycemia was instilled by some early writers following the discovery of insulin. It was an unwise warning, which did much harm and cost many lives. The general practitioner was literally afraid to use insulin, and many are still afraid to use it and advise their patients that insulin is only the last resort in the treatment of diabetes. It will take time and a great deal of educational work to counteract this fear.

The best illustration I* can give that the general practitioner is actually afraid of insulin is my own experience in cases of coma in children. In my series of 218 cases of diabetes in children over a period of thirteen years there were fifty cases of coma. Of these fifty patients I treated thirty-one and the remaining nineteen were treated by the family physician during the emergency. Of the thirty-one whom I treated, five died one in the preinsulin era and three one hour after admission, having been in coma for a long time before reaching the hospital and arriving in a moribund state. Of the nineteen patients treated by the family physician, sixteen died. I feel that the fault lies not so much in the physician as in the early writings on insulin, which frightened him so that he will not use insulin except as a last resort, when it is obviously too late to accomplish anything. This should be a lesson to all.

One thing to bear in mind in cases of coma is that insulin does not exert the same action per unit as it does in a noncomatose patient. It takes a great deal

more insulin to bring about the same results. Large doses should be used at the beginning. If studies of the blood sugar content are not available, one must depend on catheterized urine as a guide.

Is there any great danger from hypoglycemia? I feel convinced that, barring old arteriosclerotic patients or patients with cardiac damage, there is but little or no danger. Furthermore, hypoglycemia is easy to counteract. A few cubic centimeters of a solution of dextrose intravenously will correct the condition in a few minutes. When I see the numerous nondiabetic patients who have chronic hypoglycemia, with values ranging in the thirties and forties for over long periods of time, I fail to be convinced that hypoglycemia lasting for a few minutes in a case of coma jeopardizes the patient's life. The danger is more from too little than too much insulin. I do not mean that insulin should be used promiscuously without any consideration for the patient. It should be used wisely, but to use it wisely one needs laboratory data and experience.

The symptoms of hypoglycemia have been described so often and so thoroughly that I need not dwell on

them here. Usually profuse perspiration, a rapid pulse rate and a certain type of pallor are indicative of this condition.

OTHER MANIFESTATIONS

Acidosis and Alkalosis.—As acidosis leads up to coma, one is therefore apt to see the patient in the precomatose stage of acidosis. There is another condition which one should bear in mind in the differential diagnosis which is very similar and for that reason I am stressing it. This condition is just the opposite of acidosis, namely, a condition of alkalosis. Table 4 shows how similar these two conditions are.

Coma Without Acetone in the Urine.—Acetone in the urine, while an almost constant accompaniment in diabetic coma, may not be present during this emergency, as there are many cases of this type on record in the literature.⁹ It is the same with this as any other diagnostic problem in medicine—no one sign needs to be present in all cases and it is apt to be lacking in any given case. Because acetone is not found in the urine, one must not be misled.

COMPLICATIONS IN COMA

There are several complications that may arise during the progress of the emergency of diabetic coma. The foremost is perhaps cardiac embarrassment. Bowen² reported two cases in which clinical paroxysmal auricular fibrillation developed during coma. Both patients recovered. Borg⁹ reported a case in which several attacks of diabetic acidosis and coma occurred, the last two attacks being accompanied by auricular fibrillation. The case is indicative of the etiologic relation of acidosis to auricular fibrillation and to ensuing myocardial insufficiency. Insulin relieved the auricular fibrillation. Caffeine, epinephrine and digitalis administered intramuscularly are recommended by various authors. In cases of profound cardiac collapse, strophanthin, $\frac{1}{120}$ grain (0.5 mg.), should be given intravenously.

Anuria and oliguria have been reported as occurring during a state of coma.¹⁰ This must be dealt with promptly. I have seen but two patients with this type of case and in both the use of Fischer's solution intravenously cleared up the condition.

When a patient is unconscious, one must watch for distention of the bladder, which will occur periodically and require catheterization.

Infections of various kinds—otitis media in children, mastoiditis, acute appendicitis—are apt to be present, for these often lead up to coma and must not be missed. In fact an acute abdominal condition is often present and I do not know of a harder problem to solve. One can never be absolutely certain whether one is dealing with merely a comatose state with abdominal symptoms or coma plus acute appendicitis. When a problem like that is presented, one should share the responsibility with a surgeon so as to play safe with the patient as well as with oneself. Many a patient has been operated on for acute appendicitis and a normal appendix has been found, to the great chagrin of the surgeon. However, when there is any doubt and the diagnosis seems reasonably certain, an operation should be performed. It is a serious matter, however, to operate on a patient in coma, and the closest supervision is necessary on the part of the physician. Thus far, fortunately, I have not encountered such an emergency, although I have seen many patients in coma with signs of appendicitis.

SUMMARY

1 Diabetic coma presents a major medical emergency, which must be dealt with promptly, efficiently and adequately.

2 The treatment rests on two main aids—insulin and liquids. These are of primary importance. There are other accessory aids.

3 The outcome in cases of diabetic coma depends largely on how early the treatment is started. The longer treatment is delayed, the poorer the patient's chance for recovery.

4 Coma still presents a high mortality rate, the average as given in the literature being in the neighborhood of 20 per cent.

5 Complications during coma, such as cardiac embarrassment, anuria, overdistention of the bladder and infections, may arise, and they should be dealt with promptly.

GLANDULAR PHYSIOLOGY AND THERAPY

THE THYMUS GLAND

L. G. ROWNTREE, M.D.

Director Philadelphia Institute for Medical Research
PHILADELPHIA

NOTE.—This article and the articles in the previous issues of THE JOURNAL are part of a series published under the auspices of the Council on Pharmacy and Chemistry. The last will appear in the next issue. When completed the series will be published in book form.—Ed

Uncertainty has characterized our knowledge of the thymus gland from ancient down to modern times, its function has remained a riddle. Despite the fact that the gland occurs in all higher animals and in lower orders down to primitive fishes, its nature is not understood. By some it is considered a gland of internal secretion, by others a part of the lymphatic system or a vestigial structure. Though epithelial in origin, the gland becomes lymphoid in character at birth or with advancing years. Pappenheimer¹ regards it as an epithelial rather than as a lymphoid organ, an assumption that has not been proved. Cowdry² states that "the thymus undergoes lymphoid transformation as vestigial structures, i.e., the vermiform appendix, have a tendency to do."

The thymus together with the parathyroids arises from the third and sometimes from the fourth branchial clefts, the thymus from the ventral and the parathyroids from the dorsal diverticulum. The thymus and parathyroids, therefore, are intimately associated in their development, and recent work would seem to indicate that they may possibly share some functions in common. Parathyroids are frequently embedded in the thymus gland. The thymus anlage descends in the neck, the gland locating finally in the lower part of the neck or upper part of the thorax. The thymus usually consists of two adjacent lobes. In some animals it presents the so-called neck and heart thymus. Under the microscope it is seen to consist of a cortex and a medulla. Within the medullary portions are concentrated the well known but little understood characteristic structures called Hassall's corpuscles. These are considered by some as epithelial in type and by others as reticular cells capable of phagocytosis. A secretory function has not been established. Obviously ignorance prevails.

Careful studies on the growth and development of the thymus gland have been made by various workers by Hammar³ (1906 to 1929), by Bratton⁴ (1925) and by Young and Turnbull⁵ (1931) of the Status Lymphaticus Committee working under the auspices of the National Research Council of Great Britain. It is obvious that knowledge of the normal development is

This work has been aided by a grant from the American Philosophical Society.

essential to recognition of the abnormal development of the thymus gland. It is unfortunate, therefore, that no general agreement has been reached concerning the weight of the thymus in infancy and early childhood, that is, at the age when status thymicolymphaticus is most prevalent. Hanmar found the thymus weight at birth to be 12 Gm., at 5 years 23 Gm., at 10 years 26 Gm., at puberty 37.5 Gm., at 20 years 25 Gm. Young and Turnbull, however, give the average weight of the thymus at birth as 21.3 Gm. and find a gradual increase until puberty to 34 Gm., after which the weight gradually diminishes so that at midlife it is in the neighborhood of 15 Gm. Despite failure to establish an accepted weight in the first years of life, it seems to be proved that the thymus is relatively and absolutely largest during the period of greatest growth, and that the gland begins involution at puberty and thereafter diminishes in size.

Although the literature on the thymus is unusually voluminous, little is known at present concerning its function. Hoskins⁶ states that "more and more research of recent years has continued to cast doubt upon the thymus as a member of the endocrine congregation." Information concerning the function of the thymus is gleaned from two sources: physiologic studies in the laboratory and clinical observations on patients together with correlated observations at autopsy. Physiologic investigations on the thymus gland comprise chiefly the effects of its removal at different ages and of the administration of thymus extract or of the feeding of thymus substance.

Friedleben⁷ in 1858 carried out extensive studies leading to the belief that the thymus is not indispensable but that it has an important bearing on blood formation and on nutrition and growth. Basch⁸ (1902) emphasized its importance in the young, claiming that thymectomy in the young results in a form of osteomalacia or rickets. He believed that the thymus was concerned in some way with growth and with the calcification of bones. Its relation to calcium metabolism has also been suggested by the work of Hewer⁹ (1914) and Nitschke¹⁰ (1929), as well as the work on eggs, which will be commented on later. The work of Basch was followed by that of Klose and Vogt¹¹ (1910 to 1914). According to their observations, thymectomy in the young was followed by a latent period, then adiposity and finally a period of cachexia, in which nutritional disturbances and spontaneous fractures occurred followed by death. Next came the excellent, careful criti-

cal review by Park and McClure¹² (1919) of the work on the thymus from the time of Restelli¹³ (1845) down to the year 1919. These investigators also recorded their own experiments, which led them to the opinion that extirpation of the thymus probably does not influence growth and development. They concluded that:

- 1 The thymus gland is not essential to life in the dog.
- 2 Extirpation of the thymus produces no detectable alteration in the hair, teeth, contour of the body, muscular development, strength, activity or intelligence of the experimental animal.
- 3 Extirpation of the thymus probably does not influence growth and development. The possibility that it may cause retardation in development and delayed closure of the epiphyses, however, cannot be excluded absolutely.
- 4 Extirpation of the thymus probably produces no alterations in the organs of internal secretion. It is possible that it produces well marked changes in the organs of internal secretion in the period immediately following thymectomy, which was not covered in our experiments.

Work on birds has furnished some interesting considerations. Soli stated in 1910 that thymectomy in pullets results temporarily in the laying of eggs without shells. Oscar Riddle¹⁴ found that pigeons occasionally lay eggs deficient in shell and at autopsy these birds showed defective thymus glands. Dried thymus substance fed by him to such pigeons led to the laying of normal eggs.

As a result of feeding thymus glands to tadpoles, Gudernatsch¹⁵ found in 1913 that they grew more rapidly and some reached enormous size prior to metamorphosis. This led to the thought that thymus furnishes an important growth stimulus. These results were subsequently confirmed by Uhlenhuth,¹⁶ who explained them on an entirely different basis, i. e., one of nutrition. Gudernatsch accepted the explanation that the results were due "merely to thymus diet as food."

Probably the most important and convincing work yet reported is a series of investigations carried on in Asher's laboratory.^{16a} Wiktor Nowinski¹⁷ administered an aqueous thymus extract called "thymocrescin" to rats and found that, given daily, it overcame the loss of weight of animals incident to a vitamin-free diet. The extract stimulated growth, overcame vitamin deficiency and increased the size of the gonads.

Despite all these experiments and thousands of others which for lack of space cannot be quoted, doubt has continued to exist relative to the function of the thymus gland in the minds of most physiologists, endocrinologists and clinicians. It may be said with truth that physiologic studies have in no way affected modern medical practice so far as thymus therapy is concerned.

Clinical studies have also contributed something to our knowledge of the thymus. The gland varies greatly in size in various conditions. There is enlargement in exophthalmic goiter, Addison's disease, acromegaly and status thymicolymphaticus, and supposedly in certain cases of myasthenia gravis and rickets. The enlarge-

ment in exophthalmic goiter is considered by some authorities to be in the nature of a compensatory hypertrophy. There is also enlargement after hypophysectomy and adrenalectomy. It is persistent in eunuchs and its involution is delayed in victims of early castration. The gland is diminished in size after puberty, this fact led Swale Vincent to propose the hypothesis that nor-

Weight curves of thymus test rats and their controls. C controls, F₁ second generation of test rat, F₂ third generation, F₃ fourth generation, F₄ fifth generation, F₅ sixth generation, F₆ seventh generation.

mal involution of the thymus is due to the development of the reproductive organs. The thymus diminishes in size in starvation, inanition, marasmus and wasting diseases generally, a fact too often overlooked. Its enlargement in Addison's disease and exophthalmic goiter constitutes an exception to this rule. The gland is subject to inflammation and infection and to syphilis and tuberculosis and is occasionally the seat of tumor formation.

Enlargement or hypertrophy of the thymus is frequently diagnosed. This has been considered of great importance because it is supposed to have led to many tragic deaths in infants and children, an association first noted by Bichat. According to Osler and McCrae¹⁸ enlargement of the thymus may be associated with (a) thymic stridor, seen commonly at or shortly after birth, (b) thymic asthma, a more exaggerated and more persistent form of stridor and (c) status thymicolymphaticus.

Status thymicolymphaticus is defined as "a condition in childhood of hyperplasia of lymphatic tissues and of the thymus in association with a flabby fat overgrowth of the body and hypoplasia of the heart and blood vessels. Pathologic examination discloses overgrowth of the body and relatively large heads, hyperplasia of the lymph glands and structures of the tonsillar ring, moderate enlargement of the external and internal lymph

glands and hyperplasia of the solitary and agminated follicles of the small and large intestine" and atrophy of the adrenals.¹⁹ "The thymus is enlarged, swollen and soft, the bone marrow is hyperplastic and in young adults the yellow is replaced by red marrow, a small heart and small aorta and peripheral vessels have been found at times and an associated condition of rickets." Osler says that "what has called special attention to this condition is the tragedy of sudden death following trifling causes, the prick of a hypodermic needle, a sudden plunge in cold water but much more often in anesthesia either ether or chloroform, when an amount has been given not in itself lethal." He advances two explanations, the mechanical and the hormonal. Recently doubt has been cast on the very existence of this disease by Young and Turnbull of the British commission, appointed in 1931 for the study of status thymicolymphaticus. The sudden death that is said to characterize this condition has never been proved to be due to an excess of thymus secretion. However, the poorly developed gonads and adrenals and hypoplasia of the cardiovascular system that are found in this condition do exist at times and may have some relation to the enlargement of the thymus.

My own studies on the thymus gland have been carried out in the Philadelphia Institute for Medical Research in the Philadelphia General Hospital, in conjunction with Dr. J. H. Clark and Mr. Arthur Steinberg of Philadelphia and Dr. A. M. Hanson of Faribault, Minn.²⁰ In 1930 Dr. Hanson prepared an extract from the thymus which he called "karkimolysin" for use in the treatment of cancer. We undertook to determine its physiologic and biologic effects on rats. Dr. Hanson's thymus extract is an acid aqueous extract of the neck thymus of young calves from 2 to 6 weeks of age (the heart thymus has not yet been studied). It is a stable preparation preserved with chlorbutanol and represents 0.6 Gm of raw thymus per cubic centimeter. Locally it is nonirritating on parenteral administration and nontoxic to rats in amounts up to 5 cc.

Comparison of Thymus Treated Rats with Controls

	Average Birth Weight, Gm	Ears Open Days	Teeth Erupted Days	Hair Appeared Days	Eyes Opened Days	Testes Descended Days	Vagina Opened Days
Controls	4.6	2.5-4	9-10	14-17	14-17	30-40	60-70
F ₁	5.0	2	4-7	10-14	12-16	15-23	35-45
F ₂	5.2	1.2	1-2	4-6	4-6	5-9	25-31
F ₃	5.7	1	1	4	4-5	4-6	21-25
F ₄	5.7	1	1	3	3	4-5	18-19
F ₅	5.74	1/2-1	1/2-1	2	2	4-5	15
F ₆	4.7	At birth	At birth*	1-2	1.5-2	2-4	15

* On first inspection or within 24 hours

Hanson believes that the active substance represents a product of the epithelial and not of the lymphatic cells.

In our work, white rats of the Wistar strain have been injected intraperitoneally daily for sixteen months with an extract of the thymus prepared by Hanson.²¹ In the first generation (F₀) treated test animals were heavier, bred more frequently and had larger litters of

20 Rowntree L. G., Clark J. H. and Hanson A. M. The Biological Effects of Thymus Extract. *Am. J. Physiol.* to be published. The Biological Effects of Thymus Extract (Hanson). *Science* 80: 274 (Sept. 21) 1934. *J. A. M. A.* 103: 1425 (Nov. 10) 1934.

21 My collaborators and I have been fortunate in having available a large supply of thymus extract of apparently uniform potency, this was prepared by Dr. A. M. Hanson in 1930 and was bottled in special molded resistance glass having a low alkali content.

heavier average weight per rat. Little of note appeared in the second generation in the first six litters cast, but in the later litters (the seventh to the eleventh) precocity appeared. In the tenth and eleventh litters the animals were larger than normal, teeth erupted on the second day and the eyes opened on the tenth day.

In the animals of the third to seventh (F_2 to F_6) generations, striking and accruing precocity, acceleration in growth and development, were noted in the offspring of each succeeding generation under treatment. The normal rate of growth and development and the precocity resulting from continuous administration of thymus extract through succeeding generations is shown in the accompanying table. The increasing growth as indicated in the weight curve is shown in the accompanying chart. Similar effects were not observed from thymus feeding.

Because of the astounding precocity, a study of the chemistry of the rats' blood was undertaken, which revealed definite changes in the calcium and phosphorus content. Whereas in our control rats the calcium content was from 9 to 11 and the phosphorus from 3 to 4 mg per hundred cubic centimeters of blood serum in the thymus test animals from the second to the fourth generation the blood serum calcium increased to from 11.4 to 13.3 with an average of 12.3, and the inorganic phosphorus reached from 4 to 7.5 with an average of 6.1 mg per hundred cubic centimeters. This would seem to have some definite bearing on the rapid skeletal development observed in the young. A study of hemoglobin content and of red and white cell counts by Dr. Lansbury²² showed no deviation from normal.

Roentgen studies of the skeleton made at weekly intervals in collaboration with Dr. L. Einhorn and Dr. B. P. Widmann revealed marked differences between the skeletons of the controls and those of the seventh generation of thymus treated rats. In the test animals (1) there is an increase in all dimensions, particularly in the length of the diaphyses of the long bones for the actual age of the animals, (2) the centers of ossification of the epiphyses of the long bones are visible earlier, (3) the centers of ossification of the epiphyses of the long bones and the vertebrae calcify and unite earlier.

The effects of thymus extract on the heart, studied in conjunction with Dr. McMillan, Dr. Bellet and Mr. Steinberg, revealed the facts that small doses have little or no effect on the cardiac action and that large doses depress blood pressure and cause death through inducing complete auriculoventricular heart block. This may be of interest perhaps in relation to sudden death in status thymicolymphaticus.

It is doubtful whether our work has progressed sufficiently far to throw any light on the question of status thymicolymphaticus. Suffice it to say that the continuous administration of thymus extract (Hanson) results in marked precocity in the offspring of treated parents after the second generation. The young show increased growth and development, especially marked in the glandular structures of the intestine but they show no susceptibility to sudden death from fright, the use of the hypodermic needle, immersion in cold water or from operation or anesthesia. So far as we are concerned the condition status thymicolymphaticus is still *sub judice*.

²² Lansbury J. J., Clark J. H. and Rowntree L. G. Lesions of the Thymus Gland as noted in 25,000 Autopsies unpublished paper.

From the foregoing it is apparent that there is still a state of ignorance rather than of enlightenment relative to the thymus gland. More work is necessary on the thymus from the standpoint of biology, embryology, histology, physiology, pathology, pediatrics and clinical medicine.²³ Our own work indicates that thymus extract, when administered continuously through successive generations of parents leads to striking, accruing precocity in the growth and development of successive generations of young. Thymus extract increases the fertility of adult rats. The young of the third and succeeding generations grow and develop physically, sexually and psychically at an unbelievable rate. They do not, however, become giant rats, as the rapid rate of growth decreases from the second month on. From our experimental studies it would seem desirable to consider the thymus gland clinically in conditions involving problems of fertility in adults and of growth and development in infancy, and in early childhood, probably also in disturbances attending puberty. A clinical trial in these fields is being made at the present time.

Therapeutics

THE THERAPY OF THE COOK COUNTY HOSPITAL

EDITED BY BERNARD FANTUS, M.D.
CHICAGO

NOTE.—In their elaboration these articles are submitted to the members of the attending staff of the Cook County Hospital by the director of therapeutics Dr. Bernard Fantus. The views expressed by various members are incorporated in the final draft for publication. The series of articles will be continued from time to time in these columns.—Ed

THERAPY OF URTICARIA AND OF ANGIO-NEUROTIC EDEMA

OUTLINE BY DR. THEODORE CORNBLEET

Urticaria is a symptom complex the characteristic lesion of which is the wheal. The lesion is fugacious and itches. There may be other symptoms and signs, but generally these are less significant.

The diagnosis of urticaria is just the beginning of the consideration of the case, as this is not a disease in itself but merely visible evidence that the subject is reacting to something to which he is hypersensitive. Urticaria can be produced not only by substances taken into the body but also by things that are touched, that are inhaled or that come close to the patient. And, in addition to these, agents may be present in the subject's body or be elaborated there which produce urticaria. Thus the list may include substances as far apart as foods or drugs, materials or objects one works with, harbored parasites such as tapeworms, a sinusitis or other focus of infection, a constitutional ailment such as leukemia, infectious processes such as septicemia, hypersensitiveness to some physical agent such as cold, or even emotional disturbance. The list of possibilities is indeed bewildering, unless one adopts a systematic evaluation of all of them in any given case. This systematic consideration of the possibilities must be tailor made to fit the individual. To the extent that

²³ In work carried on with Dr. A. H. Einhorn retardation of growth in the offspring has been encountered following thymectomy in successive generations of parents.

the search is done in a routine way, there will be a saving of time, money and trouble, and greater assurance of success. Foremost among all measures in apprehending the cause of the urticaria is a good physical examination of the patient and the obtaining of a history by logical, common sense questioning.

As there is a considerable difference between the treatment suitable to acute and to chronic urticaria, this will form the basis of its division.

ACUTE URTICARIA

1 *Causal Treatment*—Evacuation (a) Emesis induced shortly after the ingestion of the offending or suspected food (e g, shellfish, strawberries) will remove that which may still be in the stomach. In children, this is preferably secured by Syrup of Ipecac, a teaspoonful or two followed in ten minutes by a large draft of lukewarm water and, if there is no emesis, another dose of syrup in another ten minutes, continuing in that way until evacuation of the stomach has occurred. For adults, one might prefer a hypodermic injection of Apomorphine Hydrochloride, 5 mg, which usually does not produce emesis earlier than ten minutes after the administration.

(b) Cathartic. A saline should be preferred because of its rapid action, e g, a tablespoonful or two of Magnesium Sulphate, which might be administered, for best possible disguise, in effervescent ice-cold lemonade. For children, Solution of Magnesium Citrate in wine-glassful doses every two hours, until the effect is secured, might be preferable.

Diet (a) No food should be allowed the first day, and beef tea and hominy the following day, with rice and next oatmeal gruel being added to the diet on succeeding days. Salt, sugar and gelatin (which have never been reported to cause allergy) may be admitted freely as desired. Bacon, dates, lentils and kidney beans, spinach, parsnips, rhubarb and brussels sprouts may also be admitted early, as these are among the foods to which people seem to be least sensitized. Foods that most commonly cause allergy are wheat, eggs, milk, chocolate, tomato, cabbage, orange and potato. Hence these should be added last, best successively, to enable one to scrutinize the effect of each addition.

(b) In cases with an obstinate tendency to relapses, it might be well to start out with an absolute milk diet. One should give milk, buttermilk or cream and seltzer water (equal parts) every two hours for three days. This may make the patient worse if he is hypersensitive to milk, whereupon it and its derivatives will have to be rigidly excluded from subsequent diets. If he is not hypersensitive to milk, it will make the planning of the diets much easier.

(c) One may then resort successively to allergy diagnosis diets (Rowe's "elimination diets"), carefully observing the effect of each change in diet.

ALLERGY DIAGNOSIS DIETS (ROWE'S "ELIMINATION DIETS")

DIET 1—*Rice and Lamb*—Absolutely no foods other than those specified in this diet are to be used. If the patient is not sensitive to milk, he may have it in addition to the other articles prescribed in this diet.

Prescribed fruits can be used in drinks, salads, and for dessert, jams and sauces. Calories must be increased by plenty of sugar, oil and the type of starch allowed.

Gravies and sauces can be thickened only with the flour prescribed as, for instance, rice flour in this diet.

The rice must not be fried with butter, lard or any other fat except the one specified, which is olive oil in this diet.

Bread is not permitted in this diet.

Illustrative Menu—Breakfast Rice boiled, natural or fried in olive oil and served with sugar or preferably maple syrup, also peach or pear may be used.

Coffee without milk or cream, unless the patient is found not sensitive to these.

Pears and peaches, fresh or canned, a large helping.

Lemonade with plenty of sugar.

Milk, if permitted, as much as desired.

Dinner and Supper Soup Lamb broth with rice, carrots, spinach, lettuce or rhubarb.

Salad Lettuce with pears, peaches, unstuffed olives, olive oil, lemon juice.

Meats Roast lamb, broiled or fried lamb chops with rice flour and olive oil (Gravy as desired, but must be thickened with rice flour only).

Vegetables Spinach, carrots, lettuce, rhubarb, large helpings.

Dessert Lemon gelatin, pear or peach, as much as desired. Filbert nuts as desired or rhubarb sauce sweetened with sugar or maple syrup.

Drinks A lemonade with plenty of sugar, black coffee milk, if permitted.

Miscellaneous As much as desired of sugar, salt, olive oil, gelatin, maple syrup, olives (black or green, but unstuffed).

DIET 2—*Rice, Rye and Fish*—No meats are allowed in this diet, fish is used instead, if the patient is sensitive to fish but not to eggs, substitutions are indicated. The only bread allowed is Rye-Rice or Ry Crisp Rye-Rice bread is made as follows: one-third cup rye flour, two-thirds cup rice flour, 6 level teaspoonfuls Royal Baking Powder (which does not contain any egg), 4 level teaspoonfuls sugar, one-fourth teaspoonful salt, two-thirds cup water, one-half teaspoonful shortening. This recipe makes eight small muffins.

Illustrative Menu—Breakfast Cereal rice boiled, natural, served with apricot, pear or sugar, or fried in olive oil and served with molasses.

Bread Rye-Rice or Ry-Crisp.

Fruits Pineapple, prunes, apples, large helpings.

Drinks Tea, milk if tolerated, juices of the fruits already mentioned.

Dinner or Supper Soup Vegetable soup of lettuce, carrots, peas, beets, rhubarb.

Bread As for breakfast.

Salads Lettuce, beets, pineapple, olives (unstuffed), prunes with olive oil.

Vegetables Lettuce, carrots, peas and beets, rhubarb with rice, if wanted.

Dessert Pineapple gelatin or prunes, apples, large helpings.

Filberts if desired. Rhubarb and apple sauce sweetened with sugar or molasses.

Miscellaneous Sugar, salt, gelatin, olives, molasses and filberts.

DIET 3—*Tapioca, Rice and Beef*—Butter, lard or other fats must not be used except the one specified, which is Wesson Oil in this diet. Bread is not yet permitted.

Illustrative Menu—Breakfast Cereal Rice boiled, natural, served with peaches or pear juice or sweetened with sugar or maple syrup, may be fried with Wesson Oil. Tapioca baked with peaches and sugar or maple syrup and flavored with grapefruit juice.

Fruits Grapefruit, pears or peaches, liberal helping, also apples.

Drinks Grapefruit juice sweetened with plenty of sugar, coffee, milk (if permitted).

Dinner and Supper Soup Beef broth with rice, string beans, celery.

Salad Tomatoes, celery, string beans, peaches, grapefruit, pears sweetened with sugar and sprinkled with Wesson Oil.

Meats Roast or broiled beef with gravy or rice flour fried with Wesson Oil if desired
Vegetables String beans, sweet potatoes, celery and rhubarb
Dessert Grapefruit, gelatin or peaches, pears Filbert nuts as desired. Apples or rhubarb sauce sweetened with sugar or maple syrup
Miscellaneous Sugar, salt, Wesson Oil, gelatin and maple syrup

DIET 4—Corn and Chicken—Gravies and sauces may be thickened only with the flour prescribed, as for instance, corn-starch in this diet. The corn must not be greased or fried with any butter, lard or any other fat except the one specified, which is Mazola Oil in this diet.

Bread is not permitted yet, unless one wishes to use corn pone, which is made with corn meal and water or corn meal mush fried in maize oil or bacon fat, which may be eaten with prune or apricot juice or plain sugar syrup.

Illustrative Menu—Breakfast Cereal Corn, fresh or canned, taken with milk if allowed or may be fried with maize oil, salted, or sweetened with sugar and served with pineapple, apricots or prunes, cornflakes are allowed. Bacon, if desired. Molasses preferred to sugar.

Bread Corn pone as described.

Fruits Pineapple, apples and prunes as much as desired.

Drinks Pineapple or prune juice sweetened with plenty of sugar, tea with milk if allowed.

Dinner and Supper Soup Chicken soup with corn, peas, artichokes or asparagus.

Salad Artichokes squash, asparagus with pineapple, prunes and apples sprinkled with Mazola Oil.

Meats Chicken, boiled or fried with bacon fat or Mazola, gravy thickened with cornstarch, bacon as desired.

Bread Corn pone as described.

Vegetables Asparagus, squash, peas, rhubarb artichokes, large helping.

Dessert Pineapple, gelatin or prune or apples with filberts. Apple with rhubarb sauce sweetened with sugar or molasses.

Drinks Same as for breakfast.

Miscellaneous Sugar, salt, Mazola and molasses.

2. Alterative Treatment—Under the term "alterative" may be classed any remedy that, without producing symptoms of its own, corrects phenomena of disease. Such therapy is most likely to be resorted to in conditions of altered susceptibility such as "allergy," a condition in which with the present ignorance of the essential nature of the altered reactivity of the system one must necessarily blunder along with remedies "until one succeeds."

PRESCRIPTION 1—Calcium Lactate

R	Calcium lactate	30.00 Gm
	Lactose	30.00 Gm
Mix label	Teaspoonful in water every four hours on arising at bedtime and midway between meals	

(a) As there is a strong suspicion that abnormal calcium metabolism has something to do with transudative phenomena, the administration of calcium may seem rational. If it is to do any good, it must be administered freely and continued for a considerable time after improvement has set in, for increase of the quantity of ionized calcium in the blood by means of calcium administration is rather difficult to attain and when attained it is but transient. As one calcium salt is as poorly absorbed as another, Calcium Lactate (prescription 1) is the most eligible, because less irritative and not so unpleasant as Calcium Chloride (prescription 2), unless the desire to exert also an acidic influence leads one to prefer the latter. In some cases calcium seems to act very well. It is, however, frequently disappointing.

(b) Acids, as they tend to increase the ionization of calcium, might conceivably be useful, e. g., Diluted Hydrochloric Acid 2 cc given in lemonade, which is to be sipped through a tube during and after meals.

(c) Alkali is, curiously enough, more frequently and perhaps more successfully employed. It must be remembered, in possible explanation, that alkali likewise modifies calcium metabolism by causing a tendency to precipitation of the ionized calcium and that in certain

PRESCRIPTION 2—Calcium Chloride

R	Calcium chloride	15.00 Gm
	Syrup of glycyrrhiza	250.00 cc
Mix Label	Tablespoonful in half glassful of water every hour or two until relieved then teaspoonful four times daily	

cases it might be such precipitation—let us say in the capillary endothelium—that may be desirable modification. While intestinal acidity favors absorption of calcium its utilization by the tissues may be favored by alkali. It is indirect alkali, such as Potassium Citrate (prescription 3) that should be used for this purpose rather than bicarbonate, which, by its alkalinity may lessen calcium assimilation. It must be remembered, however, that urticaria may be caused or aggravated by citrate.

PRESCRIPTION 3—Potassium Citrate

R	Potassium citrate	30.00 Gm
	Syrup of orange	60.00 cc
	Water	to make 120.00 cc
Mix Label	Teaspoonful in water every two to four hours	

From what has been said, it will be understood that it is entirely rational to use calcium, acid and alkali therapy in succession to each other until the desired result has been secured.

3. Symptomatic Treatment—Lessening vagotonia

(a) Epinephrine is almost as valuable a remedy for urticaria as it is for asthma. Solution of Epinephrine Hydrochloride is injected intramuscularly in doses of from 0.5 to 1 cc. It acts promptly, but its benefits are likely to be gone in fifteen or twenty minutes. Massage of the place of injection may reintroduce some of the epinephrine into the circulation and renew the effect. It may be injected as often as required.

(b) Ephedrine Sulphate (0.06 Gm capsules, one three times daily) may lessen the necessity for the frequent injection of epinephrine.

(c) Atropine Sulphate in 0.5 to 1 mg doses, up to tolerance, may accomplish a similar result in a different way.

Analgesics also act as systemic antipruritics. Probably the most useful are (a) Salicylates, e. g., Phenyl Salicylate 0.3 Gm capsules, of which two may be taken after meals and at bedtime, (b) Acetanilid 0.20 Gm tablet every two to four hours as required. Opiates are contraindicated in this condition, as they make the itching worse.

PRESCRIPTION 4—Phenol Calamine Lotion

R	Phenol	2.50 cc
	Calamine lotion	250.00 cc
Mix Label	Dab on affected part as frequently as required to avoid scratching	

Local antipruritics must be used as required to prevent scratching. (a) Lotions. Sponging the affected part with an alkaline solution (e. g., 4 per cent sodium bicarbonate) as hot as can be borne and followed, without drying, by dusting with talcum powder, is one of the simplest procedures. Sometimes an acid lotion is more effective, e. g., vinegar 1 part to water or alcohol 2 parts. Calamine lotion combines the cooling effect of fluid with the protectant action of a powder application. The addition of 1 per cent of phenol (prescription 4)

increases its antipruritic value. Calamine Liniment, possibly with phenol, might be preferable if the skin is harsh and dry. To prescribe it, one simply substitutes the word "liniment" for "lotion" in prescription 4. Coal Tar lotion may be secured by prescribing Solution of Coal Tar, which is to be diluted 1:20 or even 1:10 or by ordering it ready for use (prescription 5). This is an intrinsically antipruritic application admissible if there are no lesions due to scratching.

The chief value of any one of these applications is to prevent scratching, which not only brings out new wheals but also inflicts damage to the skin, which on healing provokes renewed itching and scratching, a vicious circle.

(b) Baths. These are indicated if the eruption is generalized. A warm alkaline bath is prepared by dissolving a cup of sodium bicarbonate in the bath water. The addition of a demulcent makes this even more

PRESCRIPTION 5—Coal Tar Lotion

R Solution of coal tar 12 50 cc.
Water to make 250 00 cc.
Mix. Label: Sponge itching part as required (Contraindicated if there are many lesions due to scratching)

soothing, particularly if there is secondary irritation from scratching. For this purpose two or three cupfuls of cornstarch may be stirred in after the sodium bicarbonate. Instead of the cornstarch, one may use bran or oatmeal, boiled to a soft consistency, placed in a muslin bag and this squeezed out into the bath, the bag to be used also to mop the lesions with. Acid baths, though generally less effective than the alkaline baths, are sometimes useful. They can be prepared by adding a cup or two of vinegar or 15 cc of hydrochloric acid to the bath. Following the bath, the skin should be patted with a soft towel to remove excess of moisture, not rubbed dry, and dusted with talcum or other powder.

PRESCRIPTION 6—Mentholated Talcum

R Menthol 0 25 Gm
Alcohol 5 00 cc
Talcum 50 00 Gm
Mix. Label: Dust freely on itching part.

(c) Powders. Sprinkling liberally with an antipruritic powder is sometimes sufficient. A simple one as good perhaps as any, is 0.5 per cent Menthol in Talcum (Prescription 6).

CHRONIC URTICARIA

1 *Causal Treatment*—It is in chronic cases that a most exhaustive study may be required to determine the fundamental nature of the patient's dyscrasia. Among the means to locate the cause must be included blood examination for syphilis, malaria and leukemia, examination of the stools for parasites, and examination of the urine for hematoporphyrin. Treatment addressed to the underlying disease, arsphenamine if there is syphilis or quinine if there is malaria, may cure an otherwise baffling case. A basal metabolism test may lead to the administration of thyroid with decided benefit. Roentgen and other examinations may lead to the discovery of a pathologic condition in the lungs or in the sinuses. In addition, the diagnostic procedures of allergy (q.v.) may succeed in shedding light on the case, although great caution is necessary in interpreting the results, for in a patient with urticaria any injury to the skin is likely to be followed by a wheal. The foregoing allergy test diets may help in arriving at a diagnosis, although dietary regulations are, as a rule, less successful in chronic urticaria than in the acute form.

2 *Alternative Treatment*—In chronic urticaria, alternative treatment aims at desensitization. This may be specific, if the exciting cause can be determined and is of such nature as to render exposure to it unavoidable. More commonly it must be nonspecific.

(a) Peptone (prescription 7), administered perorally, is no doubt the simplest method of attempting non-specific desensitization.

PRESCRIPTION 7—Peptone Capsules

R Peptone 15 00 Gm.
Divide into thirty capsules
Label: Take one capsule an hour before meals

(b) Calcium gluconate (10 cc of 10 per cent solution) injected intravenously every other day, or, indeed, the intravenous injection of almost any other fluid, even of 1 cc of Distilled Water or of Physiologic Solution of Sodium Chloride, may suffice to induce a "colloidoclastic crisis" in these allergic individuals with their delicate systemic colloid balance, producing a change that may have a satisfactory therapeutic result but that may also be followed by a very disagreeable "reaction" without the desired relief.

(c) Autohemotherapy, which consists of injecting into the gluteal muscles from 5 to 10 cc of the patient's own blood withdrawn just previously from the cubital vein, is another measure of this kind.

(d) Typhoid vaccine injected intravenously (see Iritis) is a still more powerful appeal of this kind.

3 *Symptomatic Treatment*—The symptomatic treatment of chronic urticaria is very much like that found useful in acute urticaria.

ANGIONEUROTIC EDEMA (GIANT URTICARIA)

Angioneurotic edema, a localized form of acute transitory edema, is considered to be a special form of urticaria. The pathology of it is a mere exaggeration of that found in ordinary urticarial lesions. If the swelling occurs in loose tissues, such as those below the eye, few subjective symptoms occur. If tissues that are more bound down are affected, such as those of the hands, the symptoms are quite intense, the patient complains of a feeling of tightness, burning and itching.

Like other allergic conditions, angioneurotic edema runs in families so that it is apt to be found in several related persons. The most important thing to watch for in treating a patient with angioneurotic edema is edema of the glottis. The patient should be warned about the possibility of this dangerous condition occurring at any time in the future. He should be told to seek aid immediately if any symptoms or signs occur in his throat, even though these are very mild and just beginning. He should be warned not to wait, because the swelling comes on very rapidly with possibly disastrous results if not taken care of immediately. The mortality rate in angioneurotic edema is quite high, owing to death from edema of the glottis with strangulation.

Treatment of edema of the glottis consists of intubation of the larynx. Of course, if something more immediate is required and an extreme emergency exists, one is justified in doing a tracheotomy.

The treatment of angioneurotic edema otherwise resolves itself into that used in urticaria. The immediate measures are the same as those used in acute urticaria (q.v.). If the swelling involves a mucosa, an astringent lotion may be used with advantage. For this purpose Solution of Aluminum Subacetate may be used, one part to eight parts of water.

Focal infection, such as in the sinuses, gallbladder or appendix, has apparently been the basis of a goodly number of cases, so that one does well to hunt for these possibilities in all cases of chronic angioneurotic edema

Council on Pharmacy and Chemistry

REPORTS OF THE COUNCIL

THE COUNCIL HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORTS
PAUL NICHOLAS LEECH Secretary

DIGITOL-MULFORD (SHARP & DOHME, INC.) REACCEPTED

Digitol Mulford (Sharp & Dohme Inc) has recently been before the Council, since the three year acceptance period for inclusion in New and Nonofficial Remedies has expired, reacceptance of this product has been made by the Council on Pharmacy and Chemistry every three years since its original inclusion in New and Nonofficial Remedies in 1912. There was published a Notice of Judgment (N J 22335) in which it was charged that a shipment of Digitol was found to have almost double the potency represented by the company—"Tincture Digitalis U S P Strength". In view of this, pharmacologic assays were made during the spring of 1935.

Specimens of Digitol were purchased from retail drug stores in four widely separated parts of the country and submitted to a well known pharmacologist.

Results By comparison with the fatal dose of ouabain, 0.0005 mg per gram, the fatal dose of three specimens of Digitol were 0.0052 cc., 0.0063 cc and 0.0065 cc. The fatal dose of the fourth specimen, standardized Dec 22, 1928, was 0.0075 cc., i. e., about 15 per cent too weak. As the corresponding fatal dose of tincture of digitalis U S P is from 0.0055 cc to 0.0065 cc per gram of frog, Digitol was found to be neither weaker nor stronger than the U S P tincture.

In the routine examination of the material for Digitol submitted by Sharp & Dohme, Inc, the labels, carton and circulars were found to be satisfactory. The Council voted that the product be reaccepted for New and Nonofficial Remedies.

HO-MO-SOL NOT ACCEPTABLE FOR N N R

Ho-Mo Sol, said to be identical with Sanizone, is a solution of sodium hypochlorite and sodium carbonate with a claimed content of 1 per cent available chlorine. Both products are marketed by the Sanox Company of Toledo, Ohio, and the former, proposed for lay distribution, was presented to the Council.

The following is the account of the discovery of Ho-Mo-Sol, as stated in the folder, which is intended for public distribution.

Long ago the sponsors of HO-MO SOL sensed the need of a DIFFERENT and a BETTER Antiseptic Deodorant to effectively replace those previously marketed and accepted only because men of Science had been unsuccessful in perfecting the Germicidal Agent that carried no harsh irritants to the skin and other delicate membranes. They sought to create a Formula superior in quality to any previously employed—a Germicide that would find employment in all phases of Surgical and other Hospital irrigations, general home and industrial usage, and particularly to the field of Feminine Hygiene—one that left no unsightly stains when applied to cuts or abrasions—in short a Sanitant and Deodorant of chemical purity and crystal clarity that would effectively assist Nature in healing and cleansing by completely arresting germ growth.

A further statement in the folder is

HO-MO SOL is a Hypo-chlorite embracing an Oxygen-carrying principle hitherto unknown.

It is difficult to understand in what way this formula is superior to the well known standard chlorinated soda solution and in fact, no proof of such superiority has been submitted. Hypochlorite solutions are well known under nonproprietary names, there is no warrant for the application of a proprietary name, nor can there be any valid reason for marketing the same product under two different names each equally noninformative.

The therapeutic claims for Ho-Mo-Sol are exaggerated to an unwarranted degree. The product is recommended in "Athlete's foot," burns, cuts and abrasions, feminine hygiene, insect bites, poison ivy, prickly heat, sunburn, and as a nasal spray, gargle and mouth wash, and vaginal douche. Comment seems trite that possible errors in self diagnosis among such a widely varied group of indications might lead to grievous or serious misuse of the product in lay hands, this without consideration of whether or not hypochlorite solutions are particularly effective in all the conditions enumerated. Certain it is that, in many instances, other preparations or modes of therapy are, ordinarily, distinctly more efficacious and; therefore preferable.

A detailed discussion of the fallacies involved in the unstinted use of hypochlorite for many of the recommended conditions would be beyond the scope of this report, but it may at least be said that the habitual or repeated use of 1 per cent solutions of positively charged chlorine can produce a significant degree of local tissue damage, every surgeon is familiar with the chemical debridement accomplished by the Carrel-Dakin routine.

The Council declared Ho-Mo-Sol not acceptable for New and Nonofficial Remedies because it is an unessential modification of a standard hypochlorite solution, marketed under a non-informative, proprietary name and promoted among the laity with therapeutic claims beyond those allowed by the Council in connection with antiseptics.

CORRECTION

Ephedrine Sulphate—In New and Nonofficial Remedies, 1935, page 203 under the standards for ephedrine sulphate (sixth paragraph, giving the tests for limit of chloride) for 'dissolve 0.005 Gm of ephedrine sulphate' read "dissolve 0.5 Gm of ephedrine sulphate."

Committee on Foods

THE COMMITTEE HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORT
RAYMOND HERTWIG Secretary

NOT ACCEPTABLE

VELVETEX—BART'S CREAM BREAD

The Bart's Bakery, Inc., Savannah, Ga., submitted to the Committee on Foods "Velvetex—Bart's Cream Bread Sliced," a white bread prepared by the sponge dough method, containing patent flour, water, sucrose, vegetable shortening, powdered skim milk, yeast, sodium chloride, malt extract, a yeast food containing calcium sulphate ammonium chloride, sodium chloride and potassium bromate, and acid calcium phosphate.

Discussion of Name and Advertising—The name "Velvetex"—Bart's Cream Bread implies the presence of cream in substantial quantity in the baking formula, sufficient to give the bread qualities and nutritional values not possessed by the usual white bread, cream is not an ingredient and skim milk is the only milk product constituent. The name is inappropriate and misleading.

The advertising contains such claims as

"Not only is Bart's Cream Bread a health food. You tune into mealtime healthfulness with Bart's Cream Bread because it's healthful. It's the pure health-giving ingredients in every loaf that gives you the vitamins necessary to develop healthy bodies."

This bread is not a "health food," its ingredients are not health giving. No one food nor even the entire well balanced diet can give health. Many factors other than foods are necessary for health. The bread does not give the vitamins necessary to develop healthy bodies and in fact contains insufficient vitamin content to warrant mention. There is no justification for advertising of this character misinforming the public.

The manufacturer was advised of the recommendations of the Committee but has not demonstrated compliance. This product will therefore not be listed among the Committee's accepted foods.

THE SOCIAL SECURITY ACT AND THE MEDICAL PROFESSION

The Social Security Act is now law. Physicians, but only as employers and employees, will be directly interested in its provisions relating to unemployment compensation and taxes imposed on employers and employees. Hospitals and laboratories, operated for the financial benefit of their owners and shareholders, will be interested likewise in those provisions. Physicians who are in need and who are more than 65 years old may have an interest in the provisions of the act for the relief of the aged. Other provisions of the act, however, are of immediate and special interest to all physicians, such as the provisions relating to federal subsidies to enlarge and make more efficient the public health activities of the states and to aid the states in financing certain medical work.

Under the Social Security Act, a federal appropriation of \$8,000,000 annually is authorized, for allotment by the Surgeon General of the Public Health Service, with the approval of the Secretary of the Treasury, to states, counties, health districts and other political subdivisions, to aid them in establishing and maintaining adequate public health services. This appropriation is to be supplemented by another, amounting to \$2,000,000 annually, to cover the pay, allowances and traveling expenses of personnel of the Public Health Service detailed to cooperate with health authorities of any state and for the investigation of disease and problems of sanitation. Of this supplementary appropriation, the amount available for the investigation of disease and problems of sanitation will obviously be only so much as remains after deducting the authorized expenses of the personnel detailed to state work. The Social Security Act expressly provides, however, that personnel of the Public Health Service shall not be detailed to cooperate with the health authorities of any state except at the express request of the proper authorities of that state.

For allotment to the states by the Secretary of Labor, the Social Security Act authorizes the appropriation of

\$3,800,000 annually, to assist the states in promoting the health of mothers and children, especially in rural areas and in areas suffering economic distress, but allotments by the secretary can be made only on the basis of plans approved by the chief of the Children's Bureau, and the work in each state must be done by or under the supervision of the state health agency.

In addition to authorizing appropriations for the health activities described, the Social Security Act authorizes annual appropriations to aid states in carrying on certain medical activities.

On the basis of plans approved by the chief of the Children's Bureau, the Secretary of Labor is authorized to distribute annually among the states appropriations of \$2,850,000, to enable them to extend and improve, especially in rural areas and in areas suffering from severe economic distress, services for locating crippled children and for providing for children who are crippled or who are suffering from conditions that lead to crippling, medical, surgical and corrective and other services and care, including facilities for diagnosis, hospitals and after-care. No plan for this work is to be approved by the chief of the Children's Bureau unless it is to be administered or supervised by a state agency and provides for cooperation with medical, health, nursing and welfare groups and with organizations and state agencies charged with the administration of state laws providing for vocational rehabilitation of physically handicapped children.

For the blind, the Social Security Act authorizes annual appropriations of \$3,000,000, to be expended under the direction of the Social Security Board. These annual appropriations are to be used to aid states to furnish financial assistance to needy individuals who are permanently blind and are to be distributed on the basis of state plans approved by the Social Security Board. Not to exceed \$1,500,000 of this appropriation may be used, to the extent that it is matched by an equal amount by the states, to aid in locating blind persons, diagnosing the eye conditions from which they suffer and employing such persons. Plans submitted by the states for activities in this field, in order to permit approval by the Social Security Board, must contain definitions of blindness satisfactory to the board.

From the point of view of hospitals and scientific educational and charitable institutions and organizations, particular interest attaches to those provisions of the Social Security Act that exempt from liability for taxes corporations, community chests, funds or foundations, organized and operated exclusively for charitable, scientific or educational purposes, no part of the net earnings of which inures to the benefit of any private shareholder or individual. Correlated with this exemption, however, is the provision that excludes from the old-age benefits of the act employees of such corporations, community chests, funds and foundations and permits their exclusion also from the

benefits conferred by state unemployment compensation acts. Whether these exemptions will work to the advantage of the organizations that are supposed to benefit by them can be determined only on the basis of experience, for their employees may demand higher wages or more liberal terms of employment because they are denied the benefits of the act.

For the administration of certain provisions, the Social Security Act creates a new independent federal agency—the Social Security Board. The board is to consist of three members, appointed by the President by and with the advice and consent of the Senate, not more than two members of the board being members of the same political party. Other than this political limitation, the act does not provide specific qualifications for the members of the board. The primary functions of the Social Security Board seem to relate to the administration of the provisions of the act relating to old-age assistance, old-age benefits, unemployment compensation and the relief to the blind. It is charged also, however, with the duty of studying and making recommendations as to the most effective methods of providing economic security through social insurance and as to legislation and matters of administrative policy concerning old-age benefits, unemployment compensation, accident compensation and related subjects. The board must report annually to Congress on the administration of the functions with which it is charged. The absence of a specific reference to health insurance need not be construed as relieving the board of authority to investigate that matter, since health insurance falls within the meaning of the term "social insurance," which the board must investigate and with respect to which it must make recommendations.

Other provisions of the act, no less important than those which have been discussed, are of general interest but have no direct relation to health or medical activities. These include provisions for old-age benefits and grants to the states for old-age assistance, unemployment compensation, aid to dependent children, child welfare services and vocational rehabilitation, and pensions for Indians. The act imposes a graduated and increasing income tax on the wages of employees, to be paid by the employees themselves, and graduated and increasing excise taxes on employers, based on the wages paid employees but to be paid by employers.

The Social Security Act is designed to work a revolution in the social and political relations of the people and of the several states to the federal government. To what extent it is constitutional and to what extent unconstitutional is a question that *THE JOURNAL* cannot decide. Fortunately, it is not called on to do so. The sooner the question is decided by the courts, however the better it will be for all concerned. In carrying out the provisions of the act in the fields of medicine and public health, the officers charged with that duty are certain to find themselves handicapped by the scarcity of competent skilled and experienced assistants

and workers in practically every grade of service called for. But the law is now an actuality and the medical profession may be confidently expected to do its part toward carrying it into effect.

PASTEURIZATION OF CERTIFIED MILK

A significant development of interest to physicians as well as to all consumers of milk took place at the annual meeting of the Certified Milk Producers Association of America, meeting jointly with the American Association of Medical Milk Commissions at Atlantic City at the time of the annual session of the American Medical Association. A symposium was presented under the title "The Next Step in the Progress of Certified Milk." This subject, which anticipated permissive pasteurization of certified milk, was discussed from various points of view by a municipal milk inspector, a secretary of a medical milk commission, a metropolitan health commissioner, a state health officer, a representative of the United States Public Health Service and representatives of the medical profession, educators and the public. The outcome of the meeting was the adoption of a resolution¹ by which pasteurization of certified milk was endorsed but such pasteurization was not made mandatory.

The medical profession has long been interested in the purity and safety of milk purveyed to the public. Medical milk commissions sponsored by numerous local medical societies were the creation of the medical profession, stimulated by its interest in safe milk for baby feeding. The American Medical Association, through a resolution² adopted at Portland, Ore., in 1929, supported the efforts of public health authorities to provide safe milk for human consumption. This resolution by implication endorses pasteurization, which has been strongly favored by the American Public Health Association³ and the Conference of State and Provincial Health Authorities of North America⁴. Direct endorsement of pasteurization is embodied in a decision of the American Medical Association Committee on Foods⁵. The sponsorship by the medical profession of raw certified milk on the one hand and pasteurized milk on the other was not inconsistent. The value of certified milk has been great, even to those who have never used certified milk. Through the experience developed by methods of certification, the general level of sanitation in milk production has been raised. Producers of certified milk have furnished invaluable leadership in the dairy industry. At the same time the

necessarily high cost of certified milk, which rendered it inaccessible to most consumers, made necessary the availability of a supply of milk that could be relied on for safety and yet could be supplied at much less expense. Pasteurization furnished the answer to the latter need. Now that the producers of certified milk and the medical milk commissions have adopted permissive pasteurization, there should be benefit to all interested groups. Physicians desiring the highest quality of pasteurized milk for their patients will be able to prescribe pasteurized certified milk, producers of certified milk will be able to offer their customers a pasteurized product, public health authorities will be aided in their program of universal pasteurization, and milk consumers will have a wider choice among desirable milk supplies.

THE PATHOGENESIS OF GOUT

Although the association of gout with a disturbance of purine metabolism has been known for a long time, this relationship has recently become the subject of further investigation. Hench and his co-workers,¹ who compared 100 cases each of gout, rheumatic fever and infectious arthritis, point out that the first difficulty encountered in the study of gout is the correct diagnosis. The criteria for the diagnosis of gout in their study were a history of joint disease together with 5 mg or more of uric acid in each hundred cubic centimeters of blood or in tophi or both. According to these observers the clinical course of gout differs from the other disorders in that it is marked by paroxysmal and intermittent attacks associated with complete remissions before the stage of chronic gout is reached. The appearance of the objective signs of gout is so inconsistent and may be so delayed that the characteristic clinical history often affords the earliest basis for the differential diagnosis. Another difficulty in making a satisfactory diagnosis is the question of the reliability of the methods of uric acid estimation and the significance of high values sometimes found apart from gout.² Obviously a necessary preliminary to the study of gout is a redefinition and the establishment of recognized principles of diagnosis in doubtful cases.

It is encouraging to note the point of view expressed in three recent studies. Talbott, Jacobson and Oberg³ investigated the electrolyte balance in two cases during various phases of acute gout. One of the patients was under observation for twenty-two months, during which time he had fifty attacks of acute gout, twenty-one of which occurred while he was on a metabolic regimen. It was found that a diuresis began before any clinical or subjective evidence of gout became manifest

and that a negative sodium and chloride balance accompanied the diuresis. Coincident with the diuresis there was an increased excretion of potassium, calcium, ammonia, titratable acid, phosphate and urate. A diuresis from transient disturbance of purine metabolism was not excluded. Certain purine bodies are known to possess a diuretic action, and one or more of these might be formed in sufficient amounts before the attack of gout to produce an increased urinary output. This explanation would associate the diuresis intimately with the generally assumed pathogenesis of the disease. They conclude, however, that the metabolic processes associated with acute gout are not adequately defined by a description of uric acid metabolism alone.

In another series of studies of gout,⁴ diets high in fat were administered to four gouty patients. In two patients such extreme pain developed that discontinuance of the diet was necessary. In the two other patients the diets were taken for fairly long periods and in their blood the amount of uric acid was markedly higher than it had been at first. This result resembles that found in nongouty persons. In the gouty patients however, the return to normal blood uric acid levels following the discontinuance of the high fat diets was delayed as compared with that in normal persons or in other forms of joint disease. Lockie and Hubbard therefore propose the addition of the following test for differentiating gout from various forms of chronic arthritis: "Feed a diet consisting of from 250 to 350 Gm of fat, 50 Gm of protein and from 30 to 50 Gm of carbohydrate for a period of from five to seven days. If, within that time, pain in the joints has developed or if existing mild joint pains have markedly increased in severity, a diagnosis of gout must be carefully considered."

Gudzent,⁵ who has long been a student of joint disease, recently observed a patient who had a severe attack of gout every time he took milk and yet this patient tolerated meat very well. Gudzent reviewed a larger number of patients with gout and reached the conclusion that the acute attack has no connection with sudden deposits of uric acid but is an allergic reaction to a gout toxin. A number of such patients, and those with certain other forms of rheumatism, reacted to skin tests with fish, eggs, milk and other substances with wheal formation, and abstinence from these foods resulted in improvement.

Just what part these studies will play in elucidating the gout problem is uncertain. It is generally known that what is called gout is not a rare condition and that it is possibly increasing in frequency. With the refinements in technic in the study of metabolites, diet and allergic diagnosis, the knowledge of so called gout should rapidly advance.

Current Comment

SKIN IRRITANTS IN ADHESIVE PLASTER

The occurrence of skin reactions following the use of adhesive plaster is by no means uncommon, indeed, the statement has been made that approximately 1 per cent of all normal individuals show the phenomenon. According to the current opinion, two types of reactions may occur. One is simply the result of mechanical trauma by the adhesive plaster and it disappears within a short time after the removal of the plaster. The other type of reaction is a true allergic response to substances present in the adhesive base. Such reactions often increase in severity after removal of the plaster and may persist for many days. Obviously, little can be done to decrease the incidence of the reactions due to tissue trauma, however, the occurrence of the allergic manifestations might be lessened if the nature of the irritating substances were known. A recent investigation on this problem¹ has yielded interesting information. The effects of the various constituents of several different makes of adhesive plaster were determined in twenty-one subjects who had previously been shown to react to the mixture of substances present in the original tape. Eleven ingredients, namely, three kinds of rubber, pine wood rosin, "Burgundy" pitch (a mixture of resins), olibanum (a gum resin), beeswax, zinc oxide, wool fat, starch and orris root, were tested. They were applied to the skin of the arm or the back. A large number of skin reactions resulted from the application of rosin, "Burgundy" pitch, and the smoke-cured wild rubber. Reactions to the other constituents were fewer and less pronounced. Therefore it appears that the substances responsible for the allergic reactions are chiefly the resins and the wild rubber. These observations should stimulate research in the industries for the purpose of finding nonirritating types of resins and rubber to replace those now used in the manufacture of adhesive plasters.

Association News

NEW A M A RADIO PROGRAM

Beginning October 1 at 5 p. m. eastern standard time (4 o'clock central standard time, 3 o'clock mountain time) the American Medical Association with the cooperation of the National Broadcasting Company will begin a new series of programs under the same title, "Your Health," that has previously been used for the National Broadcasting Company broadcasts. This series will differ radically from any programs which the American Medical Association has ever broadcast before. Instead of fifteen minute talks, the program will be thirty minutes in length and will consist of vivid dramatizations of medical emergencies and how they are met. Into each program will be woven a short talk by Dr. Morris Fishbein or Dr. W. W. Bauer emphasizing the points illustrated in the dramatizations. Incidental music will accompany the programs. Scripts and production are being provided by the National Broadcasting Company under the supervision of the American Medical Association. Further announcements will appear in *THE JOURNAL* and in *Hygieia* and will be furnished to state medical journals and county bulletins.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

CALIFORNIA

New Requirements for Foreign Medical Graduates—The California State Board of Medical Examiners announces that after September 14 graduates of foreign medical colleges must show the following requirements, in addition to those contained in the standard application for a license to practice medicine in California:

- 1 A license to practice medicine and/or surgery in the country wherein is located the medical school which granted them their diploma.
- 2 One year internship served in an approved hospital in the United States after fulfillment of condition number 1 or
- 3 Completion of the senior course in an approved medical school in the United States in lieu of requirement number 2.

Immunization Campaign—A six weeks campaign for immunization against diphtheria and smallpox will be opened in San Francisco, August 26, under the auspices of the county medical society and the department of health. After school opens each child who does not have a positive record of immunization will receive a circular addressed to his parent stressing the importance of this procedure and urging him to consult the family physician. The health department will furnish postcards to physicians for reporting the completion of each immunization and vaccination. Physicians will follow up their own patients for return appointments for injections of toxoid and vaccination but will send back to the health department the cards of those who fail to return after four weeks. Physicians have agreed to give the treatments free to those who cannot pay, the department to furnish the serum without charge through distribution centers.

COLORADO

State Medical Meeting at Estes Park—The sixty-fifth annual session of the Colorado State Medical Society will be held at the Stanley Hotels, Estes Park, September 4-7, under the presidency of Dr. Nicholas A. Madler, Greeley. Out-of-state speakers will include Drs. Edwin P. Sloan, Bloomington, Ill., on "Diseases and Dysfunctions of the Thyroid Gland," Rosco G. Leland, Chicago, "Changes Confronting Modern Medicine," Joseph R. Plank, New Orleans, "Postoperative Treatment Based on Physiologic Principles," and Emsley T. Johnson, Kansas City, Mo., "Liver Damage Due to Synthetic Drugs, with Clinical, Postmortem and Experimental Studies." Dr. Austin A. Hayden, Chicago, will show a motion picture of the activities of the American Medical Association. Other speakers on the program will include the following physicians:

- Harry L. Baum, Denver, Treatment of Various Streptococcal Infections by Means of Human Convalescent Serum.
Ralph H. Verploegh, Denver, Immune Blood Serum in Treatment of Measles, Scarlet Fever and Septicemia.
Osborne S. Philpott, Denver, Use of Serums in Treatment of Erysipelas.
Charles O. Giese, Colorado Springs, Diagnosis of Cancer of the Lung.
Philip Work, Denver, Nonoperative Care of Head Injuries.
Joseph E. A. Connell, Denver, Surgery in Severe Head Injuries.
Robert M. Lee, Fort Collins, So-Called Subdeltoid Bursitis.
George A. Unfug, Pueblo, The Painful Shoulder. X-Ray Interpretation.
Thomas D. Cunningham and John C. Mendenhall, Denver, The General Practitioner and Allergy.
Duval Prey, Denver, Newer Concepts in the Treatment of Furunculosis.
Gerald M. Frumess, Denver, Scope and Limitations of the Term Eczema.
William M. Bane, Denver, Modern Treatment of Convergent Strabismus.
Lawrence D. Dickey, Fort Collins, Elliott Treatment in Pelvic Inflammations and Dysmenorrhea.
Thomas E. Carmody, Denver, Relation of Oral Pathology to General Disease.
Duane F. Hartshorn, Fort Collins, Better Psychiatry by the General Practitioner.

There will be symposiums on chronic arthritis, in which Drs. Thaddeus P. Sears, Constantine F. Kemper, Kenneth D. A. Allen, John G. Ryan and Charles E. Sevier, all of Denver, will participate, and one on hematuria, presented by members of the Denver Urological Society. There will be two clinical pathologic conferences. The annual golf tournament will be held at the Estes Park Country Club, Friday. A new feature of the program this year is the "social hour," held from 5 to 6 p. m. each day. Thursday evening there will be a stag smoker at the Estes Park Chalets.

IDAHO

Personal—Dr Kenneth H Collins, Craigmont, has been appointed physician and health officer of Lewis County, succeeding Dr Eli Taylor, Nez Perce, resigned

Society News—The Panhandle Medical Association was organized at a meeting in Spirit Lake, July 15, Dr John W Schori, Spirit Lake, was elected president, and Dr Alexander Barclay, Coeur d'Alene, secretary. This meeting followed a heart clinic held in the afternoon at Spirit Lake Hospital, under the auspices of the Kootenai County Medical Society and a banquet at the Spirit Lake Hotel. Dr George H Anderson, Spokane, conducted the clinic, with the assistance of Dr Arthur Betts. The new society will hold monthly meetings, membership is open to members of the state medical society in good standing.

ILLINOIS

New Standards for Milk Pasteurization—Principal features of the recently revised minimum sanitary requirements of milk are announced by the state department of health as follows:

1 The short time high temperature method of pasteurization is legalized. This method requires that milk be heated to not less than 160 F and held at that temperature for not less than fifteen seconds.

2 Plans for contemplated pasteurization plants must be submitted to the state department of public health and plans must be approved and a certificate of approval issued before pasteurized milk can be legally sold or distributed.

3 Pasteurized milk must not be delivered to consumers in any container except that in which it left the pasteurization plant. This makes illegal the retailing of dipped milk bought in bulk from pasteurizing plants and sold as a pasteurized product. Hotels and restaurants that serve milk to customers are considered consumers under the law.

4 The state department of health is required to set up and enforce the minimum sanitary requirements for downstate pasteurization plants.

5 Representatives of the department are permitted to enter and inspect any pasteurization plant at any time.

The new standards eliminate the requirement of filtering milk prior to pasteurization and prohibit filtration through cloth or wire after pasteurization. They also require the heating of foam on milk in the pasteurizing vaults to pasteurization temperatures.

Chicago

Society News—Dr Harold O Jones was chosen president-elect of the Chicago Gynecological Society at the annual meeting, June 7, and Dr Edward L Cornell was installed as president.

KANSAS

Personal—Dr Clay E Coburn, Kansas City, was elected president of the Kansas State Board of Health at Topeka, June 28.—Dr Murray C Eddy, Hays, has been named health officer of Ellis County.

Society News—Care of the indigent was discussed by Dr Forrest L Loveland and Clarence G Munns, executive secretary, Kansas Medical Society, both of Topeka, before a meeting of the Osborne County Medical Society recently. These speakers presented the same subject before the Reno County Medical Society in Hutchinson, July 18.—Speakers before the Rush-Ness County Medical Society and the Rush-Ness Public Health Council in Ness City, June 25, included Dr Murray C Eddy, Hays, on "Intestinal Obstruction."—Dr John N Sherman Chanute, was chosen president of the Southeast Kansas Medical Society at a meeting in Pittsburg in June.—Speakers before the Tri-County Medical Society (Barber, Harper and Kingman counties), included Drs Albert R. Hatcher, Wellington on appendicitis, and Fred J McEwen, Wichita, the irregular heart.

LOUISIANA

Tulane Celebrates Centennial—Tulane University of Louisiana observed its centennial anniversary in connection with its commencement, June 12. Coincident with this celebration were the special exercises of the medical department, organized in 1834 as the Medical College of Louisiana. The medical program was made up of special clinics, ward rounds and addresses by members of the faculty, June 11, and in the evening the alumni banquet was held. The program June 12, included the following speakers:

Dr Rudolph Matas, professor of general and clinical surgery emeritus at the school Contributions of Louisiana to the Surgery of the Blood Vessels.

Dr John M T Finney, professor emeritus of surgery, Johns Hopkins University School of Medicine, Baltimore, Reminiscences of the Progress of Surgery During the Last Fifty Years.

Dr George H Whipple, Rochester, N. Y., dean, University of Rochester School of Medicine, The Production and Storage of Blood Serum Proteins and Hemoglobin.

Dr James M Mason, Birmingham, Ala., A Series of Arteriovenous Aneurysms.

Dr Finney delivered the commencement address on "Medical Progress During the Past Fifty Years." The honorary degree of doctor of science was conferred on Dr Mason, and that of doctor of laws on Drs Whipple and Finney. The first lecture at the school was given on the first Monday in January 1835 and the first class graduated in 1835. The institution became the University of Louisiana Medical Department in 1847 and the Tulane University of Louisiana Medical Department in 1884. Its name was changed in 1913 to Tulane University of Louisiana School of Medicine.

MASSACHUSETTS

Personal—Dr Richard P Strong, professor of tropical medicine, Harvard Medical School, delivered the Maiben lecture in medicine before the American Association for the Advancement of Science, Minneapolis, June 25, his subject was "The Importance of Ecology in Relation to Disease."—Dr Riley H Guthrie, formerly on the staff of the Monson State Hospital, Palmer, has been appointed assistant commissioner of the state department of mental diseases.

Changes at Boston University—Announcement has been made recently of the following changes in the faculty of Boston University School of Medicine:

PROMOTIONS

Dr Leroy M S Miner to be professor of stomatology
Dr Edwin W Smith, professor of obstetrics
Dr Burnham S Walker, professor of biochemistry
Dr Clarence Wesley Sewall, associate professor of obstetrics
Fredrick F Yonkman, Ph.D., associate professor of pharmacology
William C Boyd, Ph.D., assistant professor of biochemistry
Dr John C V Fisher, assistant professor of obstetrics.

APPOINTMENTS

Richard H Norton, D.M.D., assistant professor of stomatology
Dr Phillips L. Boyd, assistant in anatomy
Dr Welman B. Christie, assistant in surgery
Dr Lucian Curtis Foye, assistant in pediatrics
Dr Thomas R. Mansfield, assistant in surgery
Dr Anthony Macaluso, assistant in ophthalmology
Dr Barnett H. Rosenfield, assistant in gynecology
Dr Carl E. Trapp, assistant in neurology.

MICHIGAN

Wayne County's Golf Tournament—The Wayne County Medical Society, Detroit, will hold its sixth annual golf tournament at the Oakland Hills Country Club, August 28. The prizes include a number of five and ten dollar checks and purchase orders.

Hospital News—The state administrative board has authorized immediate construction of a tuberculosis sanatorium in Gaylord, to cost \$250,000.—An arthritis clinic was recently organized at the University of Michigan Hospital, Ann Arbor, patients may be referred to this clinic for consultation.

Personal—Dr Thomas E Gibson, Mount Pleasant, has been appointed health officer of Genesee County, succeeding Dr Leslie A Lambert, Flint, who resigned.—Dr Duncan A. Cameron observed the completion of fifty years' service in Alpena, July 19.—Dr Floyd R. Town, who recently resigned as health officer of Jackson after sixteen years' service to become health commissioner of Isabella County, was the guest of honor at a dinner given by members of the health department staff, July 13.—Dr Edward A. Schulz, Grand Ledge, has been appointed a member of the state council of health to succeed Dr William E. McNamara, Lansing, and U. G. Rickert, D.D.S., Ann Arbor, to succeed the late Chalmers J. Lyons, D.D.S.

Dr Patten Appointed Professor of Anatomy—Bradley M. Patten, Ph.D., assistant director of medical sciences of the Rockefeller Foundation, has been appointed professor of anatomy and director of the anatomic laboratories of the University of Michigan Medical School, Ann Arbor, succeeding Dr Gotthelf Carl Huber, who died last December. Forty six years of age, Dr Patten received his degree in doctor of philosophy from Harvard University in 1914. He was assistant in zoology at Harvard from 1912 to 1914, going in the latter year to Western Reserve University Medical School, Cleveland as instructor in histology and embryology. He advanced through the teaching ranks until he became associate professor in 1921 and continued in this capacity until 1934, when he was appointed assistant director for medical sciences of the Rockefeller Foundation. He has written books on embryology, two of which are widely used textbooks, and contributed to zoological and medical journals. His investigations have been concerned chiefly with the development of the heart, the initiation of the heart beat and the changes of the vascular system at birth.

MINNESOTA

Hospital News—The new \$250,000 Indian tuberculosis hospital constructed by the federal government adjacent to the state hospital at Walker has been opened for patients, according to the *Journal-Lancet*.

Society News—*Minnesota Medicine* announces the organization of the Dakota County Medical Society. Dr L D Peck Hastings, was chosen president. The new society is the thirty-fourth component of the state organization.

Layman Abortionist Sentenced to Four Years—Peter H Nellessen, St. Paul, 64 years of age, was sentenced to four years at hard labor at Stillwater, July 25, following a plea of guilty to a charge of performing an abortion. The state board of medical examiners reports that Nellessen formerly for eight years a male nurse at the Soldiers Home at Minnehaha Falls, had been engaged in performing criminal abortions, according to his own statement, over a period of forty years. He stated that he had performed about 100 abortions during the past year. His arrest followed the discovery of a grave in the back yard of a home in St. Paul where an abortion had been performed on a sixteen year old girl.

MISSISSIPPI

No Enrolment of Freshmen—The board of trustees of the University of Mississippi adopted a resolution, July 18 instructing the school of medicine not to enroll a first year class for the session 1935-1936. This school was dropped from the approved list of the Council on Medical Education and Hospitals, July 1, 1934 without prejudice to the students then enrolled.

New County Health Officers—Appointment of the following physicians as health officers of the counties indicated is announced:

W S Martin Carthage, Leake County
William A McMahon Union, Newton County
Albert P Alexander Como, Panola County
George Lacey Biles Sumner, Tallahatchie County
Homer B Watkins, Noxapater, Winston County
Frank L McGahey Calhoun City, Calhoun County

NEW YORK

Society News—Speakers at a meeting of the Steuben County Medical Society, Bath, June 13, were Drs Heywood H Hopkins, Rochester, on "Low Back Pains", Joseph Boch, Burlington, Vt., "Bronchial Asthma Differentiated from Cardiac Asthma", and Valentine Uhjely, "Influence of Emotions on Metabolism".

New York City

Personal—Six physicians were made honorary surgeons in the police department July 18. They were Drs Erastus M Hudson, Fred S Dunn, David J Kaliski, Harold D Meeker, Andrew M Gillen and John J Cahill. There are now sixty-three honorary surgeons in the department. Dr Joseph W Miller was recently reappointed—Dr Simon R Blatteis has been appointed chief of the department of medicine at the Jewish Hospital of Brooklyn.

Approved Clinical Laboratories—Nearly 200 clinical laboratories operating under permit of the department of health are listed in a recent bulletin of the department. The list includes private laboratories, those in voluntary, private and proprietary hospitals doing work for other than hospital patients. It gives the name of the director, address of each laboratory and the type of work each is authorized to do. Laboratory permits are issued for one year.

Annual Reports of Hospitals—The Society of the New York Hospital reported recently that its net deficit for 1934 was \$756,455 which was \$178,701 less than the deficit for 1933. The operating expenditure was given as \$2,390,697 an increase of 5.5 per cent over 1933 and the operating income, exclusive of investment, was \$1,337,878 an increase of 23 per cent. A total of 64,101 patients was cared for an increase of more than 12,000—Mount Sinai Hospital reported that 14,762 patients were treated in 1934 compared with 14,335 in 1933 in the outpatient department 319,003 were treated as compared with 289,649 the previous year. Expenditures amounted to \$1,790,376.93 of which \$216,316.47 could not be covered by receipts applicable to current expenses.

A Campaign Against Noise—A concentrated attack on the din of New York will be made, it was announced August 11. Mayor La Guardia, acting on the evidence furnished by an eighteen months survey made at his request has ordered police to put on a special campaign against night noise during October. The motorcycle and traffic squads will turn their attention in November to day noises. Persons who blow automobile horns needlessly, apartment dwellers who run their radios at high pitch and shipping concerns that use trucks with

solid tires will be warned to moderate their noise-producing apparatus. By December 1 the mayor hopes to have antinoise laws drafted and offenders will be arrested. Noises made by apparatus belonging to the city will also be dulled. Fire and police cars will use their sirens only when making calls, not when returning to stations. Muffling devices will be placed on the trucks of the sanitation department until they can be replaced with noiseless equipment. A test made, August 13, with a noise meter showed that certain spots designated as the noisiest in the city in a survey in 1930 have changed little in the interim. Manhattan Bridge at Canal Street and the Bowery was found to be the noisiest spot in both surveys, with Herald Square and Times Square coming close behind. The general trend of intensity was downward, however.

NORTH CAROLINA

Society News—Dr David L Beers, Asheville, addressed the Buncombe County Medical Society, July 15, on "Circulatory Failure".—At a meeting of the Wake County Medical Society, Wake Forest, July 11, Drs Herbert M Vann, George C Mackie, Edward S King and Coy C Carpenter presented a symposium on the kidneys.

Symposium on Poliomyelitis—The Fourth District Medical Society met at Rocky Mount, July 12 to hear a symposium on poliomyelitis presented by Drs William Lloyd Aycock, Boston, Alexander G Gilham of the U S Public Health Service, Joseph C Knox, Raleigh, state epidemiologist, Carl V Reynolds, state health officer, and John H Hamilton Raleigh, head of the state laboratory.

Advisory Board on Workmen's Compensation—Governor Ehringhaus has appointed an advisory medical committee to the state industrial commission in accordance with an amendment to the state workmen's compensation law making occupational diseases compensable. Dr Samuel B McPheeters, Charlotte, is chairman, and Drs John Donnelly Huntersville, and Gibbons W Murphy, Asheville, are the other members.

NORTH DAKOTA

Personal—Dr Ira D Clark, Fargo, has been appointed to the staff of the Grafton State School, an institution for the mentally deficient, to succeed Dr Arthur S Needles who resigned. Dr Mary E W Soules, Dickinson, was added to the staff as physician for women and children.

OHIO

Floods Cause Emergent Health Situation—A critical health situation developed in Belmont County following torrential rains July 4. All water supplies, derived from 840 shallow dug wells, were contaminated by the flood waters, which had swept away sanitary facilities. There were four cases of typhoid in the area at the time the flood came. The county has not had a health commissioner since April 1934. When the emergency arose, the county sanitary inspector was empowered by the county board of health to handle the situation, but he had no funds or personnel. *Ohio Health News* reports. Two representatives of the state board of health went to Belmont County with typhoid vaccine. The sanitarian had begun chlorination of wells distributed instructions against using well water and arranged with physicians to administer typhoid vaccine. Since their visit it has been reported that 1500 persons have been inoculated and all wells have been chlorinated.

PENNSYLVANIA

Society News—Dr Frank H Lahey, Boston, addressed the Harrisburg Academy of Medicine, June 18, on exophthalmic goiter.—A symposium on syphilis was presented at a meeting of the Dauphin County Medical Society, Harrisburg, June 4 by Drs Walter D Hawkins, Robert Denison and Louis W Wright.—Dr Jesse O Arnold, Philadelphia, addressed the Fayette County Medical Society, Uniontown, August 1 on Heat Therapy—Indications and Methods of Application.—Dr Henry Harold Gelfand, New York, addressed the Wayne County Medical Society, Honesdale, July 18, on "Hay Fever Present-Day Concepts, Diagnosis and Treatment."

Philadelphia

Children Immunized—Approximately 9,000 children under 6 years old were immunized against diphtheria in a campaign sponsored by the Philadelphia Department of Public Health, June 3-21. Alum-precipitated toxoid in one dose was used. It is estimated that 50 per cent of the children under school age and 75 per cent of the school children have now been immunized. In the last ten years the death rate from diphtheria in Philadelphia has been reduced from 1610 per hundred thousand of population to 109.

SOUTH CAROLINA

Society News—Dr Carlos I Green, Orangeburg, addressed the Edisto Medical Society, June 6, on "Differential Diagnosis of Appendicitis, Salpingitis and Pyelitis"—Drs Walter J Bristol and Benjamin Rubinowitz, Columbia, addressed the Columbia Medical Society, June 10, on the hard of hearing and diagnosis of anorectal diseases, respectively

Personal—Drs Nathaniel B Heyward, Columbia, and John C Caldwell, Chester have been reappointed to the state board of medical examiners for four year terms—About 500 persons attended a reception in honor of the eightieth birthday of Dr Henry Boardman Stewart at his home near Fountain Inn, July 21 Dr Stewart graduated from Emory University School of Medicine, Atlanta, in 1879 and has practiced in the community surrounding his home for fifty-six years

WEST VIRGINIA

Reorganization of Medical School—The West Virginia University School of Medicine, Morgantown which was disapproved by the Council on Medical Education and Hospitals of the American Medical Association in February without prejudice to the students enrolled, is undergoing a complete reorganization Plans are largely matured and are being carried out as rapidly as possible in an attempt to maintain a school of small size and high standards

GENERAL

News of Epidemics—Seven cases of diphtheria were reported from the village of Toland, Pa., July 31—Nearly 400 members of a Civilian Conservation Corps camp near Clinton, Conn., were quarantined, July 30 when a case of scarlet fever was found in the barracks—Thirty-two army officers became ill of food poisoning, August 10 after eating cream pie left over from the day before, at Fort Knox, Ky

Change in Examination Date—The American Board of Ophthalmology has canceled its examination that was to have been held in Cincinnati, September 17 because of a conflict in dates and announces that the examination will be held in St. Louis, November 18, at the time of the meeting of the Southern Medical Association Applications must be filed sixty days before the meeting with the secretary, Dr William H Wilder, 122 South Michigan Avenue, Chicago

Society News—The Mississippi Valley Medical Society, including the states of Iowa, Missouri and Illinois, will hold its first annual session in Quincy, Ill., October 2-4 The plan to organize the society was approved by the Adams County Medical Society and the Marion-Ralls County Medical Society and formal organization took place, April 8, in Quincy Speakers at the coming session include Drs Isaac A Abt Chicago, William Wayne Babcock, Philadelphia, Hugh Cabot and William C MacCarty, Rochester, Minn and Albert Soland Los Angeles In addition, a clinical lecture course will be conducted during the three days

Sydenstricker Made Scientific Director of Milbank Fund—Edgar Sydenstricker, statistician of the U S Public Service and for several years director of research for the Milbank Fund, has been appointed scientific director for the Milbank Fund He will be in charge of the scientific work. Mr Sydenstricker was born in China in 1881 and came to the United States in 1896 He was educated at Washington and Lee University, Johns Hopkins and the University of Chicago From 1908 to 1915 he served as special investigator in charge of industrial community studies for the U S Immigration Commission and the U S Commission on Industrial Relations In 1915 he was appointed statistician to the U S Public Health Service and has been statistical consultant since 1928, when he was appointed director of research for the Milbank Fund In the year 1923-1924 Mr Sydenstricker served as chief of the service of epidemiologic intelligence and public health statistics for the League of Nations, helping to initiate the statistical work of the International Health Organization.

Medical Bills in Congress—*Changes in Status* S 2047, providing for the general welfare of the Indians of the state of Oklahoma, has been reported to the Senate (Senate Rept. 1232) This bill among other things proposes to authorize the erection of additional hospitals for the protection of the health of the Indians of Oklahoma S 3334 has been reported to the Senate, providing for the care and treatment of members of the National Guard, Organized Reserves Reserve Officers Training Corps and Citizens' Military Training Camps who are injured or contract disease while engaged in military training (Senate Rept 1231) H R 4513 has passed the Senate,

authorizing payment of claims for unauthorized emergency treatment rendered to World War veterans *Bills Introduced* H R 9104, introduced (by request) by Representative Rankin, Mississippi, proposes to establish a permanent medical service in the Veterans' Administration H R 9116, introduced by Representative Rankin, Mississippi, proposes to extend the provisions of veterans' laws and regulations to persons who served in Russia during the World War, and their dependents.

Poliomyelitis Outbreaks—Troops of the National Guard of the District of Columbia and Virginia have been barred from training in Maryland and Pennsylvania because of the outbreak of infantile paralysis in their home areas, according to newspaper reports, August 13 and 12, respectively In Virginia, twelve new cases reported to the state health department, August 13, brought the total since July 1 to 391 In North Carolina, where the outbreak seems to have originated, 534 cases of the disease have been reported since the first of the year During the week end of August 10, 133 new cases of infantile paralysis had been reported to the New York City Health Department Although this is the largest number of any week since the epidemic of 1931, it was stated, "there is no indication that the disease is assuming epidemic proportions" Dr Leslie L Lumsden of the U S Public Health Service was in Louisville, Ky, August 12, studying twenty cases of infantile paralysis which had occurred within the past two months In Massachusetts, one death and sixteen additional cases reported during the week end of August 10 brought the total number of cases to 176

American Child Health Association Disbands—At a meeting in New York, August 13, the American Child Health Association voted to discontinue its activities The aims and purposes for which the association was formed have been in large part accomplished, Dr Samuel M Hamill, Philadelphia, president, declared in an address at the meeting, and the expenditure of large sums of money to maintain a separate organization is no longer justified Dr Philip Van Ingen, New York, secretary, pointed out in a letter sent to members that there are now few organizations interested in health or the fighting of disease in whose programs the child does not occupy a prominent place The association was formed in 1923 by a merger of the American Child Hygiene Association and the Child Health Organization of America. Former President Herbert Hoover was president, and vice presidents were Drs. L Emmett Holt Jr, Baltimore, Livingston Farrand, Ithaca, N Y, and Thomas D Wood, New York Mr Hoover directed the policies until he went to the White House and has since been honorary president Dr Samuel J Crumline, New York, has been general executive since 1925

Malpractice Suits Delayed by Patient's Minority, a Remedy—The New York Law Revision Commission has under consideration the advisability of recommending that the New York legislature abolish the rule that permits a person to sue at any time before he is 22 years old for damages for alleged malpractice that occurred at any time during his minority If New York abolishes this rule, it will be easier for other states in which it prevails to do so Concrete evidence of the injustice arising out of the rule will make it easier to procure its abolition Prof Victor Levine professor of law, Syracuse University College of Law, Syracuse, N Y, who has been asked by the New York Law Revision Commission to draft a proposed revision of the New York statute of limitations, requests therefore that physicians report to him cases of which they have knowledge in which suits based on alleged malpractice inflicted on minors have been unreasonably postponed, to the detriment of physicians Doubtless many such cases have been settled out of court or decided in trial courts, without appeal of which Professor Levine cannot learn except as physicians who have knowledge of the circumstances report them to him

Death Rates in Large Cities—The New York City Department of Health has compiled the death rates for 1934 of twenty-eight large cities in the United States with a combined population of 27,417,026 giving comparative figures for various causes of death The crude death rate for all the cities was 11.42, as compared with 10.95 in 1933 Milwaukee had the lowest death rate, 8.16 per thousand of population, Detroit came second with 8.79 Washington D C, had the highest rate 16.72 Chicago had the lowest infant mortality rate among the five largest cities, 47.7 per thousand live births, San Francisco's, 33.2 was the lowest among the twenty-eight cities, that of New Orleans, 87.1 the highest Milwaukee also led with the lowest death rate from automobile accidents 13.7 per hundred thousand of population and New York City was second, with 15.3 Cincinnati's rate 47.9, was highest among

automobile fatalities. The general birth rate calculated for all the cities was 14.81 per thousand of population, with San Francisco's the lowest, 10.43, and Washington's, 20.25 the highest. The diabetes death rate varied from 9.7 per hundred thousand in Houston to 41.5 in Boston, the general rate was 28.5. Tuberculosis rates ran from 12.1 in Minneapolis to 106.4 in New Orleans. Louisville, Ky., had the highest death rate from diphtheria, 9 per hundred thousand and San Francisco the lowest, 0.1.

FOREIGN

British Medical Election—At the annual representative meeting of the British Medical Association in London July 19 Sir James W. Barrett, Melbourne, Australia, was elected president of the association for 1935-1936 to take the place of the late Sir Richard R. Stawell, Melbourne. Sir E. Farquhar Buzzard, regius professor of medicine, University of Oxford, was elected president for 1936-1937. The scientific session will be held in Melbourne, beginning September 10.

Personal—Dr. Edward Mellanby, secretary of the Medical Research Council of England has been appointed Fullerian professor of physiology at the Royal Institution.—Dr. Karl F. Wenckebach, Vienna recently received the Karl Ludwig medal presented by the German Society for the Study of the Circulation.—Dr. Arthur Salusbury MacNalty is chief medical officer of the British Ministry of Health and of the Board of Education, succeeding Sir George Newman, who retired in March.

Exposition of Medical Books—During the month of October there will be an exposition of medical books in Bologna, Italy, under the auspices of the city in connection with a number of medical congresses to be held there. The exposition will be in two parts, ancient books up to the seventeenth century and modern books published since the war. All publishing houses in the world are invited to send their books, which must arrive in Bologna before September 10. The committee on the exposition has its headquarters in the Palazzo d'Accursio, Bologna.

Government Services

New Hospital Beds for Veterans

More than 11,000 new hospital and domiciliary accommodations are to be provided for veterans at a cost of approximately \$20,000,000 under the terms of the Deficiency Appropriation Bill, which became a law August 12. Of this number about 8,800 are new and the remainder replacement of existing unsuitable facilities. Nearly 7,000 of the additional accommodations will be for veterans suffering from mental disorders. The Veterans' Administration issued the following list of projects and their estimated costs:

Tuskegee, Ala.	350 neuropsychiatric	\$300,000
Whipple, Ariz.	300 replacements, tuberculosis,	\$676,000
Los Angeles	150 neuropsychiatric	400 domiciliary (350 replacements), \$835,000
Livermore, Calif.	30 tuberculosis	\$75,000
Fort Lyon, Colorado	296 neuropsychiatric,	\$345,000
Newington, Conn.	administration building	35 general medical \$80,000
Bay Pines, Fla.	administration building	290 general medical 400 domiciliary \$1,185,000
Lake City, Fla.	80 general medical	\$150,000
Atlanta	80 general medical	\$180,000
Marion, Ind.	134 replacements neuropsychiatric	\$400,000
Knoxville, Iowa	300 neuropsychiatric (new boiler plant)	\$725,000
Lexington, Ky.	306 neuropsychiatric,	\$600,000
Alexandria, La.	100 general medical	\$100,000
Togus, Maine	350 replacements, domiciliary	\$350,000
Perry Point, Md.	164 neuropsychiatric	\$300,000
Bedford, Mass.	328 neuropsychiatric,	\$600,000
Northampton, Mass.	200 neuropsychiatric	\$250,000
Custer, Mich.	164 neuropsychiatric	\$300,000
St. Cloud, Minn.	328 neuropsychiatric	\$600,000
Biloxi, Miss.	350 domiciliary	\$400,000
Gulfport, Miss.	164 neuropsychiatric	\$300,000
Jefferson Barracks, Mo.	50 general medical beds and other buildings	\$195,000
Lyons, N. J.	628 neuropsychiatric	\$1,200,000
Batavia, N. Y.	administration building and	35 general medical \$80,000
Canandaigua, N. Y.	639 neuropsychiatric	\$1,200,000
Northport, N. Y.	800 neuropsychiatric	\$1,500,000
Chillicothe, Ohio	328 neuropsychiatric,	\$600,000
Dayton, Ohio	176 general medical and 750 domiciliary (700 replacements),	\$1,210,000
Roseburg, Ore.	350 domiciliary converted to neuropsychiatric	\$100,000
Coatesville, Pa.	314 neuropsychiatric	\$600,000
Columbia, S. C.	405 general medical	\$430,000
Hot Springs, S. D.	100 general medical	\$170,000
Waco, Texas	164 neuropsychiatric	\$300,000
Hampton, Va.	500 general medical replacements	\$750,000
Roanoke, Va.	492 neuropsychiatric	\$900,000
Milwaukee	300 replacements	\$350,000
Wisconsin site undetermined	236 neuropsychiatric	\$944,000
Cheyenne, Wyo.	125 tuberculosis 125 general medical	\$750,000

Report of British Medical Association on Immunization

More than a year ago, the British Medical Association appointed a committee consisting mainly of health officers and pathologists to prepare a scheme for informing the public regarding the protection afforded by the various methods now available of immunization against diseases. The committee's report has now been published. It deals with the diseases against which specific immunization may be widely applied—diphtheria, scarlet fever, measles, the typhoids and smallpox.

DIPHTHERIA

The committee states that diphtheria is not less prevalent than formerly but is less fatal. Isolation and sanitary measures have failed to control it, and it accounts for 3,000 deaths annually. Active immunization is confidently advocated. In children under the age of 8 years the preliminary Schick test may be omitted, since the great majority may be assumed to be susceptible but as a test of success should be performed from one to three months after the immunizing course. For children any of the preparations known as toxoid, toxoid-antitoxin mixture, toxoid-antitoxin floccules and alum toxoid may be safely used, but for adults preference is expressed for toxoid antitoxin mixture or floccules. On the average, 95 per cent of immunized persons are still Schick negative from three to five years after immunization.

SCARLET FEVER

Scarlet fever still presents difficulties in preventive medicine. The death rate has fallen remarkably, although the incidence has altered little. The Dick test is held to be very reliable. Immunization should at present be reserved for hospital staffs and children in a residential school where an outbreak has occurred. Two methods of immunization are used. 1. In England most workers use weekly or fortnightly injections of 500, 1,000, 5,000, 10,000 and 20,000 skin test doses. 2. In recent years the tendency has been to use a higher dose. In the United States the Dicks and others give doses running up to 80,000 or 100,000. By slow graduation of dose, reactions may be almost entirely avoided. Probably from 2 to 10 per cent of the immunized revert to the Dick-positive state within a year.

MEASLES

Passive immunity to measles can be produced by the use of convalescent serum or blood and by adult serum or blood. It may be used for postponing the danger of infection to a more opportune time or for mitigating the attack. Convalescent serum is the material of choice and should be given in the first five days after exposure for complete protection. Administration between the fifth and ninth days, or half dosage during the first five days, is used for modifying an attack.

TYPHOID

The work of Wright and Leishman during the war resulted in the production of a typhoid vaccine widely and successfully used. In the years that have followed, modifications have been introduced into the technique of manufacture. Saline suspensions have replaced broth emulsions. Work in the department of pathology at the Army Medical College has resulted in the production of a vaccine containing 1,000 million B. typhosus, 750 million each of B. paratyphosus A and B. paratyphosus B in 1 cc. of 0.5 per cent phenolated saline solution. Adults are given 0.5 cc. followed after ten days by 1 cc. Children between 12 and 15 are given half the dose and younger children one

fourth. Reactions are minimized by giving inoculations subcutaneously before the patient goes to bed and by avoiding alcohol

SMALLPOX

In this country vaccination against smallpox has greatly declined. Exemptions are so easily obtained that their percentage has risen from 5 in 1898 to 47.5 in 1932. On the other hand, only variola minor has been prevalent, with a mortality of only 3 per thousand. The committee holds that the retention of the present vaccination acts, from which exemption is so easily obtained, serves no useful purpose and only arouses opposition to other forms of vaccination. The practice officially recommended to public vaccinators (since 1929 because of the occurrence of vaccination encephalitis) of making only one insertion, instead of the previous four, is likely to result in an earlier loss of immunity

CONCLUSION

It is extremely unlikely that immunization against each disease, as it becomes practicable, can be made compulsory in this country. The proper course is to inform the public as to what can be achieved by immunization, that it is the controlled application, with infinitesimal risk, of a process that is going on continuously in a haphazard fashion, leaving behind a trail of suffering and death

Rockefeller Scholars in the United States

The Medical Research Council, on behalf of the Rockefeller Foundation of New York, has made the following award of fellowships tenable in the United States: D. F. Anderson, professor of midwifery and gynecology, Anderson College of Medicine, Glasgow; N. R. Barrett, demonstrator of anatomy and chief assistant to the surgical unit, St. Thomas's Hospital; A. C. P. Campbell, clinical tutor in medicine, Royal Infirmary, Edinburgh; and assistant lecturer in the department of pathology, Edinburgh University; D. H. K. Lee, Sharpey scholar in the department of physiology at University College, London; J. E. A. O'Connell, demonstrator of anatomy, St. Bartholomew's Hospital Medical School; Robert Walmsley, assistant in anatomy, University of Edinburgh.

The Diabetic Association: A Holiday for Diabetic Children

In a previous letter the formation of the Diabetic Association under the presidency of H. G. Wells, the writer, was reported. The association consists of patients with diabetes who have united in order to assist one another with their various experiences and to promote the interests of sufferers from the disease. Its latest activity is the provision of a holiday for diabetic children, a thing peculiarly difficult and in the case of those whose parents are not in comfortable circumstances practically impossible. The Diabetic Association is planning to take a number of children to the country for August. A suitable home has been found in pleasant country about an hour's journey from London and a number of helpers have volunteered their services. A skilled dietitian will be in attendance and a trained nursing staff will administer the treatment under medical supervision. Parents in a position to contribute to the scheme will be expected to do so, but not others.

Immunization Against Influenza

At the congress of the Royal Sanitary Institute, Prof. W. C. Topley, who occupies the chair of bacteriology and immunology at the London School of Tropical Medicine and Hygiene, said that two strains of influenza virus were being propagated in ferrets and mice and that before long it would be possible to immunize effectively against the disease. This would be one of the major victories of preventive medicine. He said that vaccination against a virus disease tended to be far more effective than vaccination against a bacterial disease.

July 12, 1935

Unusual Intestinal Infarcts

At the Dec. 19, 1934, meeting of the Société de chirurgie, Raymond Grégoire reported a case of infarct of the small intestine in which the etiology was obscure. Moulouguet was the first to direct attention to a type of infarct in which the mesenteric vessels are not occluded and which he termed "inexplicable infarct." In all, fifteen such cases have been reported. Grégoire's patient was a man 62 years of age who was taken suddenly ill with symptoms of intestinal obstruction. When first seen by Grégoire, the clinical picture was that of shock. The temperature was subnormal, the pulse was almost imperceptible, the extremities were cold, the superficial veins of the legs were distended, and the nails and hands were cyanosed.

On operation, 20 cm. of the lower ileum was found distended, black in some places and greenish in others, with yellowish free fluid in the peritoneal cavity. It was impossible to feel any pulsation in the larger or smaller mesenteric arteries. The veins were distended with dark noncoagulated blood. On account of the patient's poor general condition, resection was deemed inadvisable. A hypodermic injection of 1 mg. of epinephrine was given and immediately the loop of intestine (6 feet long) changed from black to red, the intensity of which color increased after some warm saline solution was poured over the exposed loop of ileum. The radial pulse immediately became perceptible, and the now quite well vascularized loop was replaced and the parietal incision was closed. Uneventful convalescence followed. Grégoire asks what this strange disease can be which gives rise so suddenly to such grave symptoms and yet subsides with equal rapidity.

There is in these cases the same clinical picture of anaphylactic shock that one observes in animals. Laubry and Franck maintain that the veins and capillaries of the body form a sort of peripheral motor force, which has its insufficiencies or asystoles the same as does the central motor, or heart, in distributing the blood throughout the body.

Such an asystole of the "peripheral heart" is seen in all severe intestinal infections such as typhoid or cholera, in peritonitis, in acute adrenal insufficiency and in severe nervous or toxic shock. Lumière stated that such a stasis of the capillovenous system is at its maximum in anaphylactic shock. Richet, Faure-Beaulieu and Villaret have observed in animals the distention of the abdominal vessels, especially the portal system. Such a stasis is greatly ameliorated by the administration of epinephrine.

Grégoire believes that such cases as his own can be best explained as being due to some form of anaphylactic shock. Clinically they are characterized by sudden pain, fall in blood pressure, abdominal stasis and hemorrhage from one or several of the viscera. One observes infarcts of the uterus, tubes, ovaries and pancreas to which a similar explanation of anaphylactic shock may be applied.

At the May 1 meeting of the same society, Grégoire and Binet (professor of physiology) reported the results of their work on dogs in attempting to reproduce experimentally an intestinal infarct of the type encountered clinically by Grégoire. Local anesthesia of the abdominal wall was employed instead of a general anesthetic. In the first series a generalized anaphylaxis was produced by injecting from 10 to 15 cc. of horse serum over a period of at least four weeks. A coil of small intestine was brought into the incision and a solution of heterogenous albumin was injected into the mesenteric vessels. The injections into the veins, against the vascular current, were without effect, but those into the veins were followed by a spasm of the vessels, lasting from 30 to 40 seconds but

without the production of an infarct. Injections into the wall of the coil of intestine were followed by the appearance of a round or ringlike plaque dark blue and rising slightly above the level of the adjacent serosa. In a second series an attempt was made to reproduce the Arthus phenomenon. Injections into the mesenteric vessels failed to yield any information but those into the intestinal wall were markedly positive. In animals that had not been prepared, four injections of 2 cc each of horse serum were injected on the anterior and posterior surfaces of the intestine. Eight days later the same coil was isolated and the same technic employed. This was repeated after another eight day interval and was followed by the symptoms of a generalized anaphylaxis. Locally the mesenteric arteries ceased to pulsate and the veins became distended with dark blood. Simultaneously the coil of intestine assumed a violet color and in places became black. Only two or three minutes elapsed between the time the generalized symptoms of anaphylactic shock and the signs of an intestinal infarct appeared. The authors believe that among the causes of "unexplained infarcts" such as Gregoire observed clinically there are a certain number which are due to anaphylactic shock, as their second series of experiments demonstrated. One should suspect such an etiology of intestinal infarct when the symptoms of collapse are the principal feature at the onset. At operation one finds but little mesenteric infiltration and mesenteric vessels that are not occluded. How should one treat such cases? If the vitality of the coil that presents signs of an infarction is still good and if the infarction does not involve too many coils and is recent, every effort should be made to combat the generalized anaphylaxis. It will be recalled that the local evidences of infarction receded rapidly during the operation in Gregoire's case, following the subcutaneous administration of epinephrine. If the exposed coils of intestine do not change in color in spite of all treatment directed against the generalized anaphylaxis, one will be forced to choose between exteriorization and resection of the infarcted portion of the exposed intestine.

Modified Schafer Method of Artificial Respiration

The defects of the Schafer method in cases of asphyxia are pointed out in a paper by Professor Hederer of the French Naval School at Toulon read at the May 14 meeting of the Academie de medecine. The method suggested must be carried out by two persons instead of one, which is its only disadvantage

Fig 1—Expiration. One assistant exerts pressure over the lower ribs as in the classic Schafer method. The second assistant grasps both elbows preparatory to making respiratory efforts as shown in figure 2.

over the Schafer method, obligatory in France since 1927. In the latter method the individual to whom artificial respiration is being applied lies face downward with the head turned to one side. By compression of the lower ribs during expiration an attempt is made to stimulate the diaphragmatic reflex. The criticism which Hederer makes of the Schafer method is that the volume of air entering and leaving the lungs is only about

100 to 150 cc, as compared to the normal volume of 500 cc and one of 250 to 280 cc when the Silvester method is used. Another criticism is that the pulmonary circulation is stimulated much less with the Schafer than with the Silvester method. These criticisms are based on laboratory studies in which the two methods were compared. Hederer suggests a method of artificial respiration combining, from a physiologic point of view, the advantages of the Silvester method with the prefer-

Fig 2—Inspiration. As soon as the compression of the lower part of the thorax has been completed by the first assistant, the arms are pulled upward and brought together in the median line by the second assistant in order to imitate normal inspiration.

able posture of the Schafer method. With the asphyxiated or drowned person in the prone position, one assistant exerts pressure on the last ribs with the fingers of both hands, the thumbs resting near the median line of the back. At regular intervals (Schafer method) expiratory efforts are imitated by pressure on the lower part of the thorax (fig 1). The second assistant, kneeling at the head of the person to be resuscitated, grasps both elbows and pulls the arms upward without changing the position of the head and hands of the subject. Thus inspiratory and expiratory movements are alternately imparted to the thorax by the two assistants (fig 2). The volume of air rises from 100 to 150 cc. to 250 to 280 cc. and the intra-cardiac pressure is greatly increased. It is as easy to teach this method as to teach the Schafer method alone.

Ulcer of Meckel's Diverticulum Diagnosed Before Operation

At the April 10 meeting of the Societe de chirurgie, two cases were reported, one by Deton and one by Huard, in which a preoperative diagnosis of peptic ulcer of Meckel's diverticulum was made and confirmed on examination of the specimen. Deton's patient, a youth of 18, had been operated on for appendicitis thirteen months previously by another surgeon. When seen by Deton the chief complaint was pain in the right iliac region and diarrhea. Roentgen examination of the colon about three months later did not reveal anything except a pericecal inflammation. The pain did not subside but seemed to appear about an hour and a half after eating and subsided following the next meal. Severe intestinal hemorrhages then occurred and a diagnosis of ulcer of Meckel's diverticulum was made. At operation a mass the size of a cherry was found on the upper surface of the ileum close to the mesentery and about 60 cm from the cecum. The coil of ileum with the diverticulum was resected. The specimen showed an epithelial lining of the gastric type and a round ulcer with indurated edges at the junction of the epithelial lining of the diverticulum and that of the ileum. Recovery was uneventful.

Huard was called to see a boy, aged 11 years, who had been taken suddenly ill with colicky abdominal pain and the history of having had several bowel movements containing clots and bright red blood. Palpation revealed slight tenderness a little to the right of the umbilicus. On account of the sudden severe

intestinal hemorrhage without accompanying symptoms, Huard made a diagnosis of bleeding peptic ulcer in a Meckel's diverticulum. Immediate laparotomy revealed a diverticulum the size of an adult thumb, which was resected. An epithelial lining thick and thrown into folds resembling that of the stomach was found. Near the base of the diverticulum was a large ulcer on the floor of which one could see a clot, which, on being detached, was seen to cover an open arteriole, from which the bleeding had its source.

Mondor in the discussion reported having been able to find 120 cases of ulcer of Meckel's diverticulum. Sudden intestinal hemorrhages with or without signs of perforation should always lead one to suspect, especially in children, an ulcer of a Meckel's diverticulum.

BERLIN

(From Our Regular Correspondent)

June 24, 1935

The German Roentgen Society

The Deutsche Röntgen-Gesellschaft convened in Berlin in April, under the chairmanship of Professor Frik of Berlin and Professor Baensch of Leipzig, to celebrate the fortieth anniversary of the discovery of roentgen rays. The chief topic was "Roentgenology of the Cranium." The Göttingen pathologist G. B. Gruber called attention to the destructive action of chordomas and meningiomas on the adjacent cranial bones, also to the important differences in the action of suprasellar and hypophyseal tumors. Stenvers of Utrecht discussed the changes in the cranial bones, due to brain tumors. Many tumors may be brought out directly in the roentgenogram. Speaking of encephalography, Flugel of Leipzig, after observations on about 1,500 patients, brought out that the method constitutes an indispensable addition to the neurologic examination. More than 10 per cent of the tumor cases had shown clinically no pathognomonic symptoms. The method may be regarded as harmless if it is used conservatively. If the technic of the exposures is suitable (five exposures in various head positions, so that the air dome moves about), a few centimeters of air (at the most, 20) applied by puncture of the cisterna will suffice. Lohr of Magdeburg discussed the changes in the arteriogram of the cranium due to brain tumors. He injected thorium dioxide sol, by way of the exposed carotid artery, into the vessels of the brain in more than 1,000 cases, without a fatality. The contrast medium disappears again completely from the brain. Olivecrona of Stockholm emphasized the importance of the roentgenogram in determining the indications and the operative treatment of brain tumors. If the clinical examination fails, one is nearly always able with the aid of ventriculography to determine the exact position of the tumor. To conclude from the roentgenogram what kind of tumor is involved is only conjecture. The procedure whereby, with a tube in motion, only the parts of a certain plane of an object may be roentgenographed, while the parts of all other layers are suppressed, was discussed. Although not new, it has only in recent years been developed to the extent of becoming practical. This method is important, for example, in the diagnosis of lung conditions.

The so-called subtraction procedure, described by Ziedses des Plantes of Utrecht, consists in preparing two roentgenograms of the same object—one before and one after a certain change, for example, of the cranium before and after arteriography, and covering the second roentgenogram with the diapositive of the first. Then everything lying outside the contrast medium is effaced, so that only the picture of the filled arteries remains the advantage being that it stands out distinctly.

K. F. Schultze of Berlin spoke on hysterosalpingography, emphasizing its importance in judging of the need and the results of operative sterilization. Roentgenography with a contrast medium reveals better the functional capacity of the

fallopian tube than actual inspection in connection with laparotomy. A contrast medium should be applied when palpable changes in the adnexa exist and when a married woman has been sterile for years.

A discussion arose on the treatment of malignant tumors with concentrated fractionated close-up radiation. The progress of high tension safety permits the construction of tubes the anticathode of which can be brought within 3 to 5 cm. of the surface of the skin, or, in the case of the vaginal tube, close up to the parametrium.

During the discussion, the results in the simpler skin cancers, which are of course most easily reached, were appraised less highly by Schinz of Zurich than in certain infiltrating inoperable and superficial epitheliomas unsuccessfully treated by other methods.

Organization of Blood Donors in Germany

The organization of blood donors is awakening great interest in Germany. The Städtischer Blutspendernachweis, established in the Rudolf Virchow-Krankenhaus in Berlin, has now 128 donors available, five of whom are women. A donor may furnish blood only once a month, and the amount furnished is restricted to 500 cc. The compensation for loss of time or earning power by reason of a transfusion is 15 marks (\$9). For purposes of general control each donor is provided with a record card the entries on which correspond with the entries recorded in the filing cabinet at the blood donors central. The blood donors central is in a position to furnish within a short time the donor required, previously examined as to blood group.

Since April 1, 1934, Leipzig also has had a blood donors central, which was created at the instance of Professor Morawitz and is under his direction. During the first year, 106 blood donors were furnished. Applicants were not accepted unless they were free from all signs of infectious disease, presented at least 80 per cent of hemoglobin and 4,500,000 erythrocytes, also a normal number of leukocytes with a normal distribution (no shift to the left and no eosinophilia), their veins had also to be adapted to blood transfusion. As Dr. Seggel of the Medizinische Klinik in Leipzig has emphasized, it was found necessary to make careful inquiries in regard to the moral reputation of applicants, since in a few donors greed predominated over moral principle, while occasionally a donor was found to be morally unsound. It is emphasized that "only donors of pure Aryan ancestry are accepted." As a rule they are either students or members of the national-socialist party. For each hundred cubic centimeters of blood (or fraction thereof) 5 marks (\$2) is paid in Leipzig. The Leipzig Krankenkassen do not hesitate to assume these charges. A large percentage of the donors are from the unemployed. In Leipzig the largest amount of blood to be supplied by a donor at one time is ordinarily 400 cc., only in an emergency may a larger quantity be taken. As a rule, if more than 400 cc. is required, two donors must be summoned. In Leipzig also no donor may be used within a month of a previous transfusion. Not only the qualities of the erythrocytes are tested but also the nature of the blood serum. In Leipzig and in Frankfurt-on-Main, donors are reexamined every three months in Berlin and in Vienna every two months. When reexamined the donor must state in writing, on his word of honor, that in the meantime neither he nor any member of his family has been affected with syphilis or other infectious disease. No examination is made immediately before the transfusion; this responsibility, as with the transfusion itself, rests on the physician in charge of the intervention. The Leipziger Krankenhaus which has undertaken the task of organizing the blood donors exacts a fee of 5 marks (\$2) to cover the general expense. During the first year of the activities of the Leipzig blood

donors' central, 420 blood transfusions were performed through its mediation. The group distribution of the 106 donors was as follows: group O, 37.7 per cent, group A, 39.6 per cent, group B, 15.1 per cent, group AB, 7.5 per cent. Of the 420 transfusions, 192, or 45.7 per cent, were performed with blood of group O, 166, or 39.5 per cent, with group A 50, or 11.9 per cent, with group B, and 12, or 2.9 per cent with group AB. Each donor supplied blood, on an average 3.96 times, each donor of group O, 4.8 times, and each donor of the AB group only 1.5 times. The cause for this differentiation does not lie in the fact that frequently unmatched blood was transfused. That occurred in only seven cases (transfusion of O blood to two patients belonging to the A group, two patients of the B group and three patients of the AB group). The donors of the O group were not examined to discover whether they were "dangerous universal donors" with a high titer of agglutinin in their blood serum. If, for some special reason, a physician desires to transfuse blood to other groups he should first convince himself that no danger is associated therewith. In Germany the certification is usually based on uniformity in the grouping of the donor and the recipient. In Paris, however, many universal donors appear to be employed. The total amount of blood involved in the 420 transfusions performed in Leipzig during the first year after the new service was established was 155,000 cc. The average amount of blood with drawn, taking all the transfusions into account was 370 cc. The 420 transfusions were received by 224 patients, 63 per cent of whom received only a single transfusion. The most transfusions (twenty one) were given in a case of panmyelophthisis, the patient, however, succumbed in spite of a total of 8,430 cc. of blood injected. Untoward incidents according to the records in the filing cabinet occurred in Leipzig in thirty cases (7.14 per cent), although the donors and recipients were properly matched. The accidents were for the most part of a mild nature, ranging from a slight to a more violent chill. In two cases the recipient developed icterus in one instance on the day of the transfusion and in another case after from eight to ten days. The causes for these manifestations were not explained. No injuries to the donors were observed in any case.

In Thuringia a group of blood donors has been organized by the Schutzstaffeln, a society formed within the ranks of the national-socialist party. There are now 210 members of this group available, their residences being widely scattered over Thuringia. The division of the blood groups corresponds to that of Leipzig, which in fact may be taken as the norm for Germany as a whole. But, in contrast with Leipzig, the dangerous universal donors of group O whose blood has an abnormally high antibody content, are eliminated by application of Coca's method. The donors in Thuringia are free from tuberculosis and syphilis and have no narcotic or alcoholic addiction. Here also blood donor centrals have been created.

Just recently the commander-in-chief of the German army issued regulations concerning the determination of blood groups in the army. It is being introduced as a routine element of the regular physical examination. For the present, all the soldiers entering military hospitals will be subjected to such a test.

The Danger of Intra-Uterine Pessaries

Recently Dr. Gesenius of the Berlin University Clinic for Women, addressed the Berlin Medical Society on the use of intra-uterine pessaries. The pessaries may be purchased without a medical prescription. Injuries and fatalities have been reported. There are several instances in which the Gräfenberg ring pessary lying in the uterus did not prevent conception. The accidents arising from the use of pessaries are so momentous that the Berlin Medical Society has decided to address a petition to the department of government having such matters

in charge, requesting that the manufacture and sale of pessaries be prohibited. The second Berlin University Clinic for Women also has reported several pregnancies (one a tubal pregnancy) during the use of the Gräfenberg pessary.

VIENNA

July 17, 1935

The Location of Carcinomas

The Austrian Society for the Combating of Cancer held recently its annual session. A report was presented by the Austrian representative, Dr. Goldschmidt, on the conference held in Paris to consider the creation of an international organization to combat cancer. The conference dealt also with a report issued by the city of Vienna which had been worked over by the statistical bureau of the city and placed at the disposal of the Austrian society. According to this report,

TABLE 1—Location of Fatal Tumors Occurring in Vienna in 1934

Organ Affected	Men	Women	Total
Face, skin and lips	84	71	155
Larynx, pharynx, mouth, jaws	162	19	171
Tongue	48	1	49
Thyroid, branchiogenic cancer	7	12	19
Mamma	6	233	239
Esophagus	87	11	98
Stomach	208	185	393
Colon	76	64	140
Rectum	100	76	182
Liver and biliary tract	30	69	99
Urogenital tract except uterus	95	158	253
Uterus		581	581
Remaining organs	146	90	236
Totals	1,045	1,560	2,605

2,996 fatal cases of tumor were observed in Vienna in 1934, only 2,605 of which were primary neoplasms. Table 1 shows the localization of these tumors.

In table 2, Dr. Goldschmidt shows what percentage of various tumors observed were amenable to a radical operation. Four groups of tumors are thus tabulated:

The low percentage of cases in which a radical operation appeared worth while is horrifying. Enlightenment of the people and improvement in medical diagnosis, would appear from these figures to be indispensable conditions. In regard to after-irradiation as supplementary treatment following radi-

TABLE 2—Percentage of Various Tumors Observed Amenable to a Radical Operation

Site of Tumor	No. of Tumors	No. Subjected to Radical Operation
Collum uteri	503	228 or 45.3%
Stomach	393	120 or 30.5%
Mamma (female)	233	177 or 76.0%
Rectum	182	87 or 47.8%

cal operations, it is noteworthy that, of 177 breast cancer patients operated on, only eighty-eight, or 50 per cent, received after-treatment with roentgen rays or radium. In view of these facts, the Austrian Society for the Combating of Cancer, in cooperation with the bureau of health of Vienna, and the radium center in the Vienna Municipal Hospital, has organized a depository of records of all cancer cases, which is already functioning in a satisfactory manner. The society plans to develop its activities further, so that a complete record of every patient operated on will be kept on file, in order that all necessary postoperative advice may be given. It was announced also that with the 110 mg. of radium belonging to

the society, which is used at the radium center in Professor Arzt's clinic in the Vienna General Hospital, a total of 15,685 milligram hours was given to cancer patients, last year

Purpura Haemorrhagica Following the Use of Allyl-Isopropyl-Acetyl-Carbamide

Of late, hypnotics and sedatives have shown an increased demand on the part of the public. There are a large number of drugs that are classed as "mild remedies," but that caution must be observed in the use of these remedies is shown by the histories of two cases reported by Dr. A. Vogel at a recent session of the Vienna Medical Society. He observed two similar cases in a man aged 68 and in a woman aged 70, who, following a small dose of allyl-isopropyl-acetyl-carbamide, developed symptoms of an essential thrombopenia, associated with a severe purpura of the skin and all the mucous membranes. There appeared petechiae of the skin, ecchymoses of the tongue, the gums and the buccal and the nasal mucosae, and hemorrhages of the gums and the nose, together with melena and hematuria. There was a complete absence of thrombocytes, and a prolongation of the bleeding time to from twelve to eighteen minutes. Pressure on the skin produced quickly large hematomas. The causal connection with the ingestion of allyl-isopropyl-acetyl-carbamide was particularly clear in the man. He had taken the preparation only twice within a period of five months, and both times, from two to three hours later, the same clinical and hematologic symptoms developed. It is noteworthy that both patients had taken the drug frequently without accident. There had been intervals of considerable length between the administrations, so that a poisoning may be ruled out, and an acquired idiosyncrasy—an anaphylactic condition—may be assumed. The "thrombocytolytic" action of the drug was exceedingly rapid. It happened that, shortly before the described attack, a blood examination of the woman had been made, which revealed the presence of 325,000 blood platelets. Ten hours after the ingestion of the drug, all the platelets had disappeared. The previous long use of the remedy without mishap is not in contravention of the conception that a sensitization had evidently occurred. In both patients the condition continued for three days, but, following two roentgen irradiations of the spleen, the symptoms disappeared completely, which was accompanied by a rapid rise in the number of thrombocytes and a return to normal of the bleeding time (from one to two minutes).

Operative Treatment of Fractures of Neck of Femur

On the basis of ninety-five cases of median fractures of the neck of the femur in which, at the Denk clinic, pegging operations were performed, corresponding lateral fractures have been operated on in a similar manner. At the last session of the Vienna Medical Society, five cases in which pegging had been done with excellent functional results were demonstrated by Dr. Felsenreich. The advantages are (1) early mobilization of all joints in favorable cases after from two to three weeks, complete weight-bearing capacity after six weeks, (2) simplification of the after-care, since, in simple cases, immediately after the operation, and in the more difficult cases three weeks later, all extension bandages may be omitted, (3) freedom from pain a few days after the operation, (4) shortening of the stay in the hospital from formerly ten to twelve weeks to from six to seven weeks at present. The early weight-bearing capacity of the leg, demonstrable in median fractures after from eight to twelve days, is not achievable in lateral fractures of the neck of the femur, because the nails used in these cases do not hold in the neck of the femur. The conception now controlling such cases as arise at the Denk clinic may be tersely expressed thus. The median fracture of the neck of the femur should and the lateral fracture may but need not be, operated on. All purely lateral fractures (that

is, those in which the whole lateral contour of the shaft and half of the distal trochanter region are still of one piece) are suitable for operation. Subtrochanteric fractures are not suitable for pegging, since the nail will not hold in the shattered subtrochanteric area. To be sure, as Prof. Dr. Hass emphasized, in case of mere epiphyseolysis of the head of the femur, bloodless reduction gives excellent results. In more than 100 cases of this kind, Professor Hass was able to restore to its position the detached epiphysis. That applies particularly to young patients. However, an operation will often shorten the duration of the healing process, and that is what Dr. Felsenreich wished to emphasize.

The Birthday of Professor Schnitzler

The seventieth birthday of Prof. Dr. Julius Schnitzler was recently celebrated by a large gathering of his pupils and admirers. Professor Schnitzler was compelled to retire recently because of legislation requiring university professors to be emeritized on reaching the age of 70. He is still in possession of his full bodily and mental vigor. His wit and his lively conversation are proverbial in Vienna. Born in Vienna as the son of the then eminent laryngologist Professor Schnitzler, he devoted himself in Vienna to the study of medicine and soon acquired prominence as a surgeon, being entrusted with the direction of the surgical department at the Vienna Polyclinic and later at the Franz-Josefs-Spital. His training in internal medicine under Nothnagel, and in pathologic anatomy under Weichselbaum, enabled him to make excellent diagnoses, while the surgical technique he learned from Albert gave him a prominent position. In 1904 he was appointed head of the surgical department of the Krankenhaus Wieden, where he remained more than thirty years. He was the first surgeon in "central" Europe ardently to defend the urgent appendicitis operation. He was also an advocate of the early ulcer operation. Surgery of the biliary ducts, of the lungs and of the pancreas is indebted to him for many important suggestions and methods.

Marriages

- THOMAS LUKE GLENNAN, Branchville, S. C., to Miss Margaret Howe of Bartow, Fla., June 14.
FRANCES E. DWORAK, Colorado Springs, Colo., to James Ryder, Ph.D., of New York, June 14.
FREDERICK LEE LIEBOLT, New York, to Miss Edith Eugenia Davis of Kansas City, Mo., May 17.
THOMAS BERNARD CARNEY, Kewanee, Ill., to Miss Katherine Mary Brugge of Chicago, June 29.
HAROLD F. SPENCER, Garnett, Kan., to Miss Margaret Frances Patton of Emporia, Kan., July 3.
PETER VOGEL, New York, to Miss Helen Mandelbaum of Mount Vernon, N. Y., June 6.
HAROLD G. POMAINVILLE, Pittsville, Wis., to Miss Bernice S. Nelson of Madison, June 18.
LEO H. McMAHON, Breckenridge, Minn., to Miss Alice Hartley of Staples, recently.
SAMUEL RAYMOND DEICH, Passaic, N. J., to Miss Helen Sara Geller of Paterson, July 3.
HUGH WILSON EIKENBERRY to Miss Everissa F. Waite, both of Peru, Ind., June 27.
MERWIN O. LANAM to Miss Frances Hobbie, both of Sioux Falls, S. D., May 26.
LEIF H. LOKVAM, Kenosha, Wis., to Miss Marian J. Owens of Madison, June 25.
EDWIN D. N. LUNN to Miss Lillian Robelen, both of Philadelphia, June 29.
THOMAS H. McCONNELL JR., Hutchins, Texas, to Miss Hazel Ditto, June 6.
JOHN A. PAYNE III, Sunbury, N. C., to Miss Mary Mundy, April 30.
LOUIS L. MARCUS to Miss Julia Olah, both of Toledo, Ohio, April 25.

Deaths

Joseph Palmer Sheppard * Little Rock, Ark., Vanderbilt University School of Medicine, Nashville, Tenn., 1900 at various times professor of genito-urinary diseases, clinical instructor in medicine and assistant in medicine University of Arkansas School of Medicine, at one time secretary of the state board of health, on the staff of the Baptist State Hospital formerly physician in charge of the Pulaski County Hospital, aged 60, was killed, July 21, in an automobile accident

Robert Hamilton Hutchinson Jr * New York, Columbia University College of Physicians and Surgeons, New York, 1905, associate professor of clinical oto-laryngology, New York Post-Graduate Medical School of Columbia University, fellow of the American College of Surgeons aged 56, member of the board of directors and on the staff of the Bronx Eye and Ear Infirmary, on the staff of the New York Post-Graduate Hospital, where he died, June 21, of uremia.

Wyman W Andrus, Miles City, Mont., Trinity Medical College, Toronto, Ont., Canada, 1893, member and past president of the Medical Association of Montana member and past president of the Montana State Board of Medical Examiners for ten years mayor of Miles City, formerly member of the state legislature at one time city health officer, on the staff of the Miles City Hospital, aged 76 died, June 17, of erysipelas

Blanton L Hillsman, Richmond, Va., University College of Medicine Richmond, 1898, formerly assistant professor of surgery (minor surgery and orthopedics), and clinical instructor in surgery, Medical College of Virginia, Richmond and associate in surgery, Medical College of Virginia, Richmond served during the World War surgeon of the police department of Richmond, aged 62, died, May 17, of angina pectoris

Franklin Welker * New York University of Pennsylvania Department of Medicine, Philadelphia 1894, president of the Medical Society of the County of New York, fellow of the American College of Physicians, director of medicine Lutheran Hospital, aged 68 died, July 17, at his summer home in Highland, N Y, of heart disease

John Joseph Murphy * Cambridge Mass Harvard University Medical School Boston 1913 fellow of the American College of Surgeons served during the World War, on the staff of the Cambridge City Hospital aged 49 died suddenly July 8 while on a vacation trip in North Conway N H of pulmonary hemorrhage.

Lee McKinstry Bryan, Philadelphia, Georgetown University School of Medicine, Washington D C, 1921 member of the Medical Society of the State of Pennsylvania served during the World War, on the staffs of the Misericordia, St. Vincent's and Delaware County hospitals, aged 43, died July 11, of heart disease

Robert Olin Simmons * Rome, Ga., Vanderbilt University School of Medicine, Nashville, Tenn., 1906 past president and secretary of the Floyd County Medical Society, on the staffs of the Harbin Hospital and the McCall Hospital, served during the World War, aged 51 died, June 29 of cardiovascular renal disease.

William Donnison Swan * Cambridge, Mass., Harvard University Medical School Boston, 1885 for many years medical examiner for the first district in Middlesex County, honorary president of the board of trustees of the Cambridge Hospital, aged 76, died, June 25, of chronic myocarditis and pulmonary edema

William Elmer Montgomery, Kansas City Mo University Medical College of Kansas City 1897 member of the Missouri State Medical Association also a pharmacist veteran of the Spanish-American War aged 61 died July 11 in the Menorah Hospital, of amyotrophic lateral sclerosis with bulbar paralysis

William Julian Spring, New York Columbia University College of Physicians and Surgeons New York 1925 on the staff of the New York State Psychiatric Institute and Hospital aged 32 died July 12 of shock and multiple fractures of the limbs and spine, as the result of a fall from a fifth story window

Harrison Worthington Howell, Wilmington Del Hahnemann Medical College and Hospital of Philadelphia 1896 at one time secretary of the Delaware Homeopathic Medical Society Examining Board formerly mayor of Wilmington served during the World War aged 62 died July 13 of heart disease

Frederick Rigby Barnes Jr * Fall River Mass., University of Pennsylvania School of Medicine, Philadelphia 1913 formerly medical examiner of the Third Bristol District Hospital aged 45, died, July 18, in the Union Hospital

Joseph W Smadel * Vincennes, Ind., University of Louisville (Ky) Medical Department, 1896, formerly member of the Second District Medical Society, member of the board of health, aged 64, died, June 30, in the Barnes Hospital St Louis, of cerebral hemorrhage

David A Beattie * San Jose Calif M.B., University of Toronto Faculty of Medicine 1892, and M.D. Trinity Medical College Toronto, Ont., 1892, medical missionary in China 1892-1894 fellow of the American College of Surgeons aged 66 died, May 26, of polycythemia vera

Maurice Worcester Turner, Brookline, Mass Boston University School of Medicine, 1889 formerly professor of theory and practice at his alma mater, on the staff of the New England Baptist Hospital, Boston, 1900-1916, aged 78, died, June 29, as the result of a fall

Pierre Pearl Burnside, Wichita Falls Texas, University of Texas School of Medicine Galveston 1933 member of the State Medical Association of Texas, formerly on the staff of the Wichita Falls State Hospital, aged 26 died, July 6 of subacute bacterial endocarditis

William Jeremiah Devlin, New Orleans, Tulane University of Louisiana School of Medicine New Orleans 1915 assistant professor of radiology Louisiana State University Medical Center, on the staff of the State Charity Hospital, aged 52, died, June 5

Lawrence Henry Hill * Colorado Springs, Colo Washington University School of Medicine, St Louis, 1907, on the staffs of the Beth-El Hospital, Gloeckner Sanatorium and Hospital and St. Francis Hospital, aged 50, died, June 9, of pneumonia.

John Byron Hull, Williamstown Mass Albany (N Y) Medical College, 1892, chairman of the board of health of Williamstown and school physician on the staff of the North Adams (Mass) Hospital, aged 75, died, July 3, of angina pectoris

Alexander Francis Irwin * Minneapolis University of Michigan Department of Medicine and Surgery, Ann Arbor, 1889, McGill University Faculty of Medicine, Montreal, Quebec, Canada, 1890, aged 69, died, May 10, of coronary thrombosis

Herbert F Saunders, Arcadia, Texas Tulane University of Louisiana School of Medicine, New Orleans 1896 aged 65 died, June 14, in St. Mary's Infirmary Galveston of pneumonia following an operation for intestinal obstruction

Asahel Clarence Lambert, Charleston, W Va Eclectic Medical Institute, Cincinnati, 1909 member of the Radiological Society of North America, on the staff of the Mountain State Hospital aged 56, died, June 8 of pneumonia

John Welch Moss, Seco, Ky, University of Louisville (Ky) Medical Department, 1917 member of the Kentucky State Medical Association aged 41, on the staff of the Seco Hospital, where he died June 30 of pneumonia

James Clyde McKay, Detroit, Vanderbilt University School of Medicine Nashville, Tenn. 1914 also a chemist served during the World War, aged 42 was found dead June 21 of chronic myocarditis and nephritis

Robert Tweedie McGibbon, Saskatoon Sask, Canada University of Glasgow Medical Faculty, Glasgow, Scotland 1919 professor of anatomy, University of Saskatchewan School of Medical Sciences aged 37, died, May 14

Homer E Tuttle, Ithaca, N Y, Chicago Homeopathic Medical College, 1896, member of the Medical Society of the State of New York aged 67, on the staff of the Memorial Hospital, where he died, July 14 of uremia

Oscar H Adamson, Georgetown, Ohio, Cleveland College of Physicians and Surgeons Medical Department of the University of Wooster, 1889, formerly county health commissioner, aged 69 died, June 4, of chronic nephritis

Charles Swenson * Braham, Minn. Hamline University College of Medicine, Minneapolis, 1903, formerly county coroner medical director and owner of the Braham Hospital, aged 58 died June 2, of chronic nephritis

Aaron Jones White, Charleston W Va Tulane University of Louisiana Medical Department, New Orleans 1914 member of the West Virginia State Medical Association aged 48 died July 1 of coronary sclerosis

Ernest William Landgraf, Omaha John A Creighton Medical College Omaha 1919 instructor in surgery at his

alma mater, aged 39, on the staff of St Joseph's Hospital, where he died, June 2, of pneumonia

Jacob Harvey, Masonville, N Y, Columbia University College of Physicians and Surgeons, New York, 1900, member of the Medical Society of the State of New York, aged 60, died, May 26, of angina pectoris

John J Lence, Jonesboro, Ill, University of Louisville (Ky) Medical Department, 1892, Missouri Medical College, St. Louis, 1893, for many years county coroner, aged 66, died, June 28, of cerebral hemorrhage

Sidney Simpson, Brownsville, Ky, Hospital College of Medicine, Louisville, 1905, member of the Kentucky State Medical Association, county health officer, aged 52, died, June 2, in St Joseph's Hospital Louisville

Myer Louis Levin & Newark, N J, University of Vermont College of Medicine Burlington, 1921, member of the board of education aged 37 died June 19, in the Beth Israel Hospital, of bronchopneumonia.

Thomas Henry Remy, Ironton, Ohio, Miami Medical College, Cincinnati, 1895, member of the Ohio State Medical Association formerly county coroner, aged 68, died, June 11, of carcinoma of the stomach

William Henry Laughlin, Milltown, N B, Canada Albany (N Y) Medical College 1893 for many years mayor of Milltown, served during the World War, aged 69, died, May 25 of heart disease

Clarence Henry Burton, Mount Clemens, Mich Detroit Homeopathic College 1901 also a dentist, member of the Michigan State Medical Society, aged 57, died, July 13, in St Joseph's Hospital

Paul Reagan Leathers, Indianapolis Indiana University School of Medicine, Indianapolis, 1927 physician in the nutrition division of the city board of health, aged 43, died, June 21 of heart disease

Thomas Abraham Owens, Toledo Ohio, University of Michigan Medical School Ann Arbor, 1932 on the staff of the Mercy Hospital aged 29, was killed, June 27, in an automobile accident

Michael J Vassel, New York, Faculte française de medecine de l'Universite de St Joseph Beyrouth Syria, 1910, aged 54, died, June 22, in the Bellevue Hospital, of cardio vascular disease

Albert C Kennedy, Patricksburg, Ind, Medical College of Indiana, Indianapolis, 1898, member of the Indiana State Medical Association, Spanish-American War veteran, aged 61, died, June 12

James Elmo Simons, Bay City Texas Kentucky School of Medicine, Louisville, 1893, member of the State Medical Association of Texas aged 65 died, June 30, of angina pectoris

Leonard George Lerner, Orono Fla Hering Medical College, Chicago 1895, served during the World War aged 68, died, June 5, in a hospital at Tampa, of rattlesnake bite

Charles Haddon Shepard, Durham, N C, Leonard Medical School, Raleigh 1901, medical superintendent of the Lincoln Hospital, aged 56 died, May 15, of cerebral hemorrhage

Hubert Wallace Wilson & Twin Falls Idaho, University of Michigan Department of Medicine and Surgery, Ann Arbor, 1892 aged 64, died, June 24, of pulmonary embolism

Frank E Wilson, Brooklyn Jefferson Medical College of Philadelphia, 1882, formerly representative in Congress, aged 78, died, July 12, of chronic myocarditis and nephritis

Eugene Wiesner, Staten Island, N Y Deutsche Universität Medizinische Fakultät, Prague Czechoslovakia, 1931, aged 30, died, June 26, of acute dilatation of the heart

Richard Frank Sitar, Minneapolis, Northwestern University Medical School, Chicago 1926 member of the Minnesota State Medical Association, aged 37, died, June 20

Arthur Clifford Johnston, Wyoming Ont., Canada Queen's University Faculty of Medicine Kingston, 1907 died, May 9 of injuries received when struck by a taxi

William P Rowland, Bevier Mo St Louis Medical College, 1888 postmaster of Bevier, aged 74, died, May 5, in the De Paul Hospital St Louis, of uremia

Robert Heber Whallon, Cincinnati Bellevue Hospital Medical College New York, 1886 aged 81 died June 18, in the Longview Hospital of coronary occlusion

Willis Daniel Storer, Los Angeles, Chicago Medical College, 1888 aged 72 died June 27 in the Good Samaritan Hospital of diverticulum of the esophagus

Morris Stark, New York, Columbia University College of Physicians and Surgeons, New York 1901, aged 58, died suddenly, July 18, of cerebral hemorrhage.

John William Whitsett, Hannibal, Ohio, Western Pennsylvania Medical College, Pittsburgh, 1903, aged 59, was killed June 24, when struck by a truck

Edwin Rodelle Moorman, Highland Park Mich, Vanderbilt University School of Medicine Nashville, Tenn., 1890, aged 72, died, June 4, of cerebral hemorrhage

George L Nicklas, Platteville, Wis Hahnemann Medical College and Hospital, Chicago, 1890, aged 72, died, June 21, of influenza and bronchopneumonia

Louis Clovis Mayrand, Deschambault Que., Canada, M.B., Laval University Faculty of Medicine, Quebec 1879, and M.D. in 1880, aged 77, died, March 27

Walter Hodge Sheldon & Madison Wis Rush Medical College Chicago, 1900, aged 60, died, June 10, of septicemia incurred while treating a patient.

James J Murphy & Pontiac, Mich, Detroit College of Medicine, 1897, aged 67 died, July 7, in the Harper Hospital, Detroit, of coronary occlusion

Waterman A Vincent & Three Mile Bay, N Y College of Physicians and Surgeons Baltimore, 1882, aged 78 died July 18 of myocarditis

Walter Harris Lucas, Lakewood, Ohio, Western Reserve University Medical Department, Cleveland, 1893, aged 62, died in July of myocarditis

Georges Bigne, Ste Anne de la Perade Que., Canada School of Medicine and Surgery of Montreal, 1903, aged 58, died, June 2 of pneumonia

John Wash Simmons, Detroit University of Tennessee Medical Department, Nashville, 1893, aged 75, died, June 29 of cerebral hemorrhage.

Elijah A Lambert, Denton, Ga, Atlanta School of Medicine 1909, aged 59 died June 21, in a hospital at Dublin of cardiac insufficiency

John Herschel Lemon, New Albany Ind (licensed in Indiana in 1897), Civil War veteran aged 90, died, July 10 of prostatic infection

Garret A Van Diest, Prairie View, Kan Rush Medical College, Chicago 1899, member of the Kansas Medical Society, aged 61, died June 4

J A Hermenegilde MacKay, Beauport Que., Canada, Laval University Faculty of Medicine, Quebec, 1927, aged 34, died March 17

Joseph Alfred Desrosiers, Bic, Que. Canada Laval University Faculty of Medicine, Quebec, 1915, aged 48 died, March 8

Joseph Holzman & Boston College of Physicians and Surgeons of Chicago 1892, aged 64 died, June 3, of arteriosclerosis

Louise Eastman, Norwood, Ohio Eclectic Medical Institute, Cincinnati, 1898, aged 76 died, June 1, of carcinoma of the lung

John Gay Williams, Los Fresnos, Texas, Miami Medical College, Cincinnati, 1892, aged 66, died, June 30, of heart disease.

Thomas W Thompson, Xenia, Ill, Rush Medical College, Chicago, 1884, aged 77, died, July 5, of cerebral hemorrhage.

George Oliver Dunseth, Tulsa, Okla, Bennett Medical College, Chicago 1910, aged 57, died, May 20, of pneumonia

Edgar O Nash, Pueblo, Colo Pulte Medical College, Cincinnati, 1881, aged 82 died in June of cerebral hemorrhage.

Robert Lee Young, Eutaw Ala, Medical College of Alabama, Mobile, 1889, aged 73, died, June 15 of arteriosclerosis.

Shelby L Wise, Galena, Ohio, Columbus Medical College, 1884, aged 76 died July 6, of arteriosclerosis

Henry Wilson Brown, Haverhill, Mass, Albany (N Y) Medical College, 1889, aged 79 died, June 6

Henry Reiter & New York Baltimore University School of Medicine, 1900, aged 55, died June 14

Alexander Pollock, Yale Mich Detroit College of Medicine 1886, aged 77 died July 11

CORRECTION

Report of Death—Dr Daniel John Townsend of Lohrville, Iowa was erroneously reported to have died in THE JOURNAL, August 10, page 451

Correspondence

PREPUTIAL CALCULUS

To the Editor—To the extensive bibliography of the paper by Dr N R Ingraham Jr, Preputial Calculus, a Clinical Rarity (*THE JOURNAL*, July 13, p 106) I wish to add the case described by D Giordano (*Compendio di Chirurgia Italiana*, Turin, Unione Tipografica Editrice Torinese 2 746, 1911) which, freely translated, reads as follows. I was asked by a colleague to see a clergyman and to be ready, eventually, to perform an amputation for cancer of the glans penis. The foreskin was abnormally distended, showing bluish veins, an extreme phimosis, a muddy fluid of foul odor leaking from the narrow passage. The palpation was painful and impressive of a stony consistency about the glans penis. When the opening was cleaned and the foreskin made to slide in various directions, a whitish surface of calcareous appearance was noticed, against which the probe produced a sound like over a stone. And such it was. A dorsal incision exposed a calcareous formation, several millimeters thick, shaped as a bell encircling the entire glans penis. The same author then quotes two similar cases from Larghi and Aquapendente.

FRANCESCO RONCHESE, M D, Providence, R I

SIROIL

To the Editor—In the Bureau of Investigation department of *THE JOURNAL* of July 27 there is an article on Siroil and in this I am named as one of the directors of the Siroil Laboratories. You no doubt have been misinformed as I have absolutely no connection with that company other than my friendship for Mr Ben Kaufmann, who has been a close friend of mine since we were boys.

About four years ago Mr Kaufmann asked me persistently to try his preparation for psoriasis, and after I saw the formula I decided it could do no harm and tried it out first on small isolated lesions and later in severe cases, with very satisfactory results. Since that time, occasionally a patient went direct to their office, and if diagnosis for psoriasis had not been made they would send the patient to me for diagnosis and would pay the usual fee.

About a year ago Mr Kaufmann in a very casual manner, thinking he was doing something for me said he had put me on his Board of Directors. This I emphatically refused and dismissed the matter from my mind so was greatly surprised to read your article. I got in touch with Mr Kaufmann immediately and he promised to write to you.

Will you please publish this letter? I have practiced medicine twenty-six years and I have yet to commit my first unethical act.

R J McCLELLAN, M D Detroit.

[EDITORIAL COMMENT—The article on Siroil stated that among the directors of Siroil Laboratories Inc there are said to be Frank V Martin Dr R J McClellan and S Meisner. This statement was based on a report from a thoroughly reliable source. In addition to Dr McClellan's letter, the Bureau of Investigation also received a letter dated August 1 from Mr Ben Kaufmann the original president of the Siroil Laboratories, in which Mr Kaufmann states that he substantiates everything that Dr McClellan has outlined in his letter. Mr Kaufmann then added: At the time that I made Dr McClellan a director of this company I did so as a courtesy to him and in recognition of our life-long friendship. I certainly never realized for one moment that this action on my part might result in the embarrassment which is his as a result of my action. I deeply regret this act of mine and I am

rectifying it immediately by withdrawing Dr McClellan's name as a director of our company." It appears therefore that the statement as it appeared in *THE JOURNAL* was technically correct, as Dr McClellan obviously has had his name withdrawn as a director only since the article appeared. Dr McClellan seems to have been the innocent victim of an embarrassing "courtesy"]

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS and queries on postal cards will not be noticed. Every letter must contain the writer's name and address but these will be omitted on request.

TUBERCULIN TEST

To the Editor—Of what value and reliability is the intradermal tuberculin (or purified protein derivative) test in infancy, youth and adult ages? Does it always show a positive in those who have some lesion no matter how mild e g nearly all adults? What would the test be like in active tuberculosis (lungs glands bone) what in quiescent tuberculosis what in recurrent tuberculosis?

MATTHEW KARASEK M D, Shidler Okla.

ANSWER—The intradermal tuberculin test, whether administered with old tuberculin or with purified protein derivative, is a test for sensitiveness of tissues to tuberculo-protein. Like all biologic tests it is not infallible, and yet it is probably the most reliable of all of them. So far as is known there is nothing that is taken into the human body in nature that results in sensitiveness of the tissues to tuberculo-protein but the tubercle bacillus. Both human and bovine strains of tubercle bacilli when growing in the human body result in a sensitiveness of the tissues. Therefore, when the tissues are sensitive to tuberculin it is good evidence that tubercle formation is present in some stage of its development, that is lesions of the first infection type of tuberculosis are present.

Once such foci of tuberculosis are developed and tubercle bacilli remain alive in or about them the tuberculin test continues to be positive as long as the individual lives. The careful pathologic studies of Robertson (*Am J Path* 9 711, supplement, 1933) have revealed the fact that large numbers of these foci contain living tubercle bacilli throughout the lifetime of the body. It is conceivable that in some instances bacilli are eventually destroyed or die out, after which there is no protein produced to keep up the sensitiveness of the tissues, hence the positive tuberculin reaction disappears. The tuberculin test, therefore is a test for the first infection type of tuberculosis and is diagnostic of that disease. Unfortunately the test gives no evidence as to the location, size or extent of the foci. Moreover, when reinfections develop, whether from exogenous or from endogenous sources, the sensitiveness of the tissues is usually changed little or not at all. Therefore the tuberculin test provides no evidence as to the presence or absence of the reinfection clinical type of disease. The test gives the same information regardless of whether the individual tested is an infant, youth or adult. It does not detect reinfection, clinical forms of the disease, whether acute or chronic, but since these are always preceded by the first infection type of disease, every positive tuberculin reactor regardless of age should be carefully examined by other methods to determine whether clinical forms of the disease are developing.

At one time it was believed that the test is of more value among infants and young children than in later life because it detected the infection nearer the time of its development. However, at that time it was thought that a high percentage of infected infants succumbed to clinical forms of tuberculosis, such as meningitis and miliary disease. Since the test has been administered in a routine way in large groups of infants and young children it has been learned that relatively few of those infected actually fall ill or die from the disease—that is, a high percentage of them tolerate it well and usually without the development of any significant symptoms. Indeed the disease is well tolerated throughout the period of childhood. The great destruction from tuberculosis in the human family begins about the period of adolescence and reaches its height at about the age of 25 years but continues to be a serious menace to health and life throughout the remainder of life's span. Therefore, if one is seeking clinical forms of tuberculosis, the tuberculin test is of greatest value during the period of adolescence and subsequently.

The tuberculin test is no longer positive in nearly all adults. The majority of adults in many parts of the country in the

teens and twenties have not been infected with tubercle bacilli and, therefore, react negatively to the test. As the number of open cases of tuberculosis in man and animals decreases through treatment, isolation, and so on, the greater will be the number of persons who reach adult life without sensitiveness of the tissues to tuberculin.

The tuberculin reaction in active, clinical tuberculosis of the lungs and other organs is not different from that in persons who have only the first infection type of disease, except that in some cases the individual develops such extensive disease and so much tuberculo-protein is liberated that the tissues become desensitized to some degree. Indeed, in some such patients the desensitization is so complete that it can be detected only by the administration of huge doses of tuberculin, but in such cases other phases of the examination usually clearly indicate tuberculosis. This is true also in some cases of acute clinical tuberculosis such as meningitis and miliary disease, even in the bodies of infants. In quiescent and recurrent tuberculosis, the tuberculin reaction does not necessarily change from that of the first infection manifestations, with the foregoing exceptions.

TREATMENT OF PERSISTENT ULCER AFTER BURN

To the Editor—Eight months ago I began treating a severe burn on a man aged 50. His entire back from the neck to the crest of the ilium and the dorsal surface of the left arm and forearm were involved with first, second and third degree burns. Tannic acid treatment was instituted in the usual way and healing progressed nicely for several months when infection occurred below the coagulum. Various methods of producing epithelial growth with marked success were used until at present there is an area over the left scapular region 3 by 6 inches unhealed. This area has a raised glistening surface that exudes a clear serous fluid which turns yellow after the dressings are left on for several hours. The edges are healthy showing no signs of inflammation or induration. Healing has for several weeks been at a standstill and no method of treatment seems to be of any use. I would appreciate advice in treating this area. Grafting has been tried on two occasions without success. Culture shows the exudate negative to bacteria. This red glistening surface is quite painful at times and most relief is afforded by the use of mercuriolate aqueous solution 1:5000. Please omit name.

M. D. Illinois

ANSWER—An ulcer that is the end result of an extensive burn is sometimes very obstinate in healing when epithelization from the edges ceases and skin grafting has been a failure. It may be necessary to resect the entire granulating surface. Following this radical procedure, thorough treatment of the wound should be done with moist dressings of surgical solution of chlorinated soda for three or four days before proceeding with the skin grafting. The preferable method of skin grafting is the Reverdin pinch graft.

A good technic to follow in skin grafting this type of ulcer is to plant the grafts (not full thickness) on the granulating area. Place one layer of very thin mesh gauze, such as the mesh in a gauze bandage, over the grafted ulcer. Gently press the islands with a moist sponge to fix the gauze. Anchor the gauze at the edges with zinc oxide and apply plenty of fluff gauze over this single layer of gauze. Allow the dressing to remain dry for six hours. At the end of this time begin wetting the dressing with surgical solution of chlorinated soda 0.5 per cent, keeping the dressing moist for five days, at which time the first dressing is done. In the event there is evidence of infection manifested by an elevation in temperature and purulent drainage showing through the dressing, the latter may be changed before the fifth day.

HIGH SUICIDE RATE OF CALIFORNIA

To the Editor—Under death rates in large cities (*THE JOURNAL*, Oct. 20, 1934, p. 1243) it is stated that San Francisco has the highest suicide rate. San Francisco has had this unenviable record for many years to my knowledge. A friend of mine much interested in seismology believes it is due to seismic disturbances. I have not been able to account for it on an economic basis for similar conditions prevail elsewhere. Have you an explanation?

HANS SCHROEDER, M.D., New Orleans

ANSWER—It is, of course, true that San Francisco has had an unenviable record with regard to the frequency of suicides for many years past. For example, during the five years 1925-1929 it was the leading city in the United States, with an average death rate of 38.8 per hundred thousand of population. In 1933 as the correspondent noted, it also stood first, with a rate of 37.6. Other California cities, such as Los Angeles, Oakland and San Diego also consistently show high rates. However, there is no evidence that seismic disturbances are the cause of this highly unfavorable showing. Very high rates prevail in other western cities outside the earthquake area, such as Seattle, Portland, Denver, Spokane and Omaha, Minneapolis, Kansas City and St. Louis have also a very high

mortality from suicide. Rates for the white population in some southern cities are likewise high. In contrast, certain eastern cities have suicide rates far below the average for the United States as a whole.

It is difficult to account for the striking geographic differences in the suicide rate in this country. The composition of the population undoubtedly plays a part—its age, sex, color and racial distribution. The large proportion of Teutonic inhabitants, in some of the cities mentioned, undoubtedly contributes to their high suicide rate, for Germanic peoples have long been noteworthy in this respect. This fact alone would lead one to distrust the causal effect of seismic disturbances on suicide. In Europe the highest suicide rates are found in Germany, Austria, Hungary, Poland and Czechoslovakia—countries where earthquakes are practically unknown. On the other hand earthquakes are prevalent in South American countries, and nevertheless Chile has one of the lowest suicide records in the world.

The whole phenomenon of suicide is far too complicated to be explained in so simple a way as the correspondent imagines. Many complex factors are involved—economic considerations, cultural patterns, religious beliefs, and, most important of all, psychologic attitudes that determine the mental and emotional reactions of the individual. It is almost impossible to isolate any one of these and point to it as the causal factor behind the suicide. Instead, one is generally confronted with a combination of circumstances which together serve as motivating forces.

In conclusion the correspondent is referred to Dr. Anita Mühl's interesting analysis of more than 500 suicides that occurred in San Diego, Calif., between the years 1911 and 1927. From a study of these data the author concludes that "this jumping-off place of the United States holds a death lure for individuals with regressive tendencies who have found it impossible to adjust themselves at one level or another." We agree with this view and think that it explains much of the excess in the Pacific Coast suicide rate.

DIABETIC NEURITIS

To the Editor—In answer to a query (*THE JOURNAL*, January 12, p. 140) regarding the treatment of neuritis in an overweight (190 pounds, or 86 Kg.) diabetic patient who has a persistent hyperglycemia, it was suggested that the patient be kept on a moderately high diet well balanced and that the insulin be omitted temporarily. There can be little doubt that if this advice is followed a higher blood sugar will result while it is well known that a normal or nearly normal blood sugar is essential for the relief of a diabetic neuritis. Fat diabetic patients even though the diabetes is mild are relatively resistant to insulin. Large doses affect the level of the blood sugar but little while a restriction of the total calories to approximately 15 or 20 per kilogram of body weight will decrease the blood sugar at a satisfactory rate without insulin. In view of the patient's age 78 liberal carbohydrate—approximately 150 Gm.—is advisable. With this allowance there need be no fear in gradually reducing the blood sugar to normal despite the popular but I believe erroneous belief that a hyperglycemia is advisable in elderly patients with diabetes.

GARFIELD G. DUNCAN, M.D., Philadelphia.

ANSWER—The original answer and the present query are not as mutually contradictory as they appear at first sight. The confusion has probably arisen from the desire of the first writer to be very brief. He undoubtedly meant a moderately high carbohydrate diet suited to the patient's needs, which would of course be a subcaloric diet in view of the patient's overweight.

It is generally agreed that a normal blood sugar is desirable for the relief of diabetic neuritis. However, it is not improbable that in this patient the pain is at least partly on an arteriosclerotic basis. Marked or sudden lowering of the blood sugar in the latter case may aggravate instead of relieve the distress as occurs in the arteriosclerotic heart. Omission of insulin, if possible, was probably advised not only on the foregoing basis but also on the clinical and experimental considerations that insulin itself may have some influence on the muscle of the cardiovascular system. The influence of the available carbohydrate and insulin on the heart have been recently reported.

Soskin, Samuel, Katz, L. N., Strouse, Solomon and Rubinfeld, S. H. Treatment of Elderly Diabetic Patients with Cardiovascular Disease. *Arch. Int. Med.* 51: 122 (Jan.) 1933.

Soskin, Samuel, Katz, L. N., and Frisch, Robert. Dual Nature of the Action of Insulin upon the Heart. *Ann. Int. Med.* 8: 900 (Feb.) 1935.

These papers do not state that hyperglycemia is advisable in elderly diabetic patients with cardiovascular disease. They do show that in some of these cases too great or too rapid reduction of the sugar available to the heart is followed by subjective and objective signs of cardiac distress. Since the amount of sugar in the blood is only a balance between that entering and that leaving the blood at any time, it may be readily understood that a high blood sugar level is not necessarily synonymous with a large supply of available blood sugar. The magnitude of the replenishing source and the rapidity of the exchange are important factors.

POSSIBLE OBSTRUCTION OF COMMON DUCT AFTER
CHOLECYSTECTOMY

To the Editor—An obese woman aged 43 had cholecystectomy nine years ago and seven small stones were found. She now complains of severe pain under the right breast passing around to the right shoulder blade. It lasts two or three days and is associated with great weakness, headaches, pain in the eyes, pruritus and light colored stools with diarrhea. Tenderness is present over the xiphoid process. What procedure for diagnosis and treatment would you suggest? Please omit name.

M D New York

ANSWER.—Local tenderness over the gallbladder, light colored stools, itching and the other systemic symptoms mentioned are suggestive of some obstruction of the common duct.

An icterus index and a van den Bergh test should be made during the attacks. The stool and urine should be examined for bile. Not infrequently an obstructing stone in the cystic duct is squeezed into the common duct or overlooked at the time of the operation. Small stones may pass out of the common duct with symptoms of colic but frequently they must be removed by operation.

Not all painful attacks after operation on the gallbladder are due to overlooked stones. Occasionally some obstruction of the common duct such as inflammation or perhaps spasm of the sphincter of Oddi may be present. Chronic pancreatitis may produce a constriction of the duct. A hepatitis may persist for some time after removal of the gallbladder and be the cause of such symptoms.

One should try medical treatment, including the instillation of a magnesium sulphate solution through a duodenal tube on an empty stomach. A careful regulation of the diet should be observed over a period of several weeks with an effort to spare the liver.

If there is evidence of common duct obstruction and no relief is obtained after a reasonable period of medical treatment, operation should be advised for exploration of the common duct. This may be quite difficult and should be thorough, as a small stone may easily be overlooked. The common duct should be sounded to determine the presence of a stricture if no stone is found. The results will determine the operative indications.

A chronic colitis may simulate these symptoms closely and, among a number of other possible conditions, should be looked for and treated if necessary.

ASPERGILLOSIS

To the Editor—A man aged 25 gives a history of a chronic cough with expectoration of a large amount of foul smelling greenish yellow sputum since childhood. He was susceptible to colds during childhood. He has been working steadily as a baker for the past five years with apparent good strength and not losing any weight. The physical examination is negative except for the presence of a few coarse rales over both bases of the lungs posteriorly. Positive cultures of *Aspergillus niger* were obtained. Roentgenograms showed multiple abscesses of moderate size in both bases of the lungs. There is also evidence of old healed abscesses. Treatment consisted of postural drainage, large doses of potassium iodide 120 grains (8 Gm.) daily for one month ultra violet therapy and small doses of creosote. There has been but little improvement in the roentgenograms since the beginning of the treatment. I have started neopraphenamine and bismuth therapy. What is the accepted treatment and the value of the autogenous vaccine? What is the incidence of aspergillosis? Please omit name.

M D Connecticut

ANSWER.—Pulmonary aspergillosis is rare in this country. Cases have been reported chiefly from France. The disease is found in pigeon feeders, hair sorters and sponge combers. Secondary invasion may occur in pulmonary tuberculosis. The treatment is that of pneumomycosis. In addition to the measures employed, roentgen therapy might be of advantage. It is doubtful whether autogenous vaccine has any value in this condition.

CRANIOTOMY IN FRACTURE OF SKULL

To the Editor—Please state under what conditions if any a craniotomy is indicated in the treatment of a fracture of the base of the skull. What are the usual procedures recommended for use in the treatment of this serious condition? Please omit name.

M D Mississippi

ANSWER.—Fractures of the base of the skull are usually fissures in the bone and are associated with symptoms of severe intracranial injury, such as loss of consciousness, stertorous breathing and marked shock. During the period of shock such supportive measures as elevation of the foot of the bed, application of heat and stimulants such as coffee by proctoclysis should be administered. The intravenous administration of a 20 per cent hypertonic solution of dextrose in amounts of 500 cc. or of a 50 per cent solution in amounts of 100 cc. can

be given not only to improve the condition of the patient but also to prevent or to reduce associated cerebral edema. After recovery from shock, roentgenograms of the head can be taken to determine the amount of injury. If the patient remains unconscious, intranasal feedings can be carried out, and magnesium sulphate retention enemas will tend to reduce the cerebral edema further. A chart should be kept on which hourly readings of the pulse rate, blood pressure and temperature are recorded. Lumbar puncture should be done in suitable cases to relieve intracranial pressure further and to remove any blood from the cerebrospinal fluid. Craniotomy is seldom indicated for fractures of the base of the skull unless there is evidence of intracranial bleeding due to an associated lesion that produces rupture of the meningeal vessels involving the cerebral hemispheres. Another condition that might prevail in which craniotomy would be indicated is increased intracranial pressure due to cerebral edema, under such circumstances, right subtemporal decompression could be done. As a rule, patients who suffer from fractures at the base of the skull and who do not respond to medical measures have usually sustained severe intracranial trauma and operation offers them but little.

HAZARDS OF COPPER PLATING INDUSTRY

To the Editor—Could there be any systemic effect from working in a copper plating department using the following formulas for copper plating steel: First solution sodium cyanide sodium bisulphite sodium thiosulphate and caustic flakes. Cleaning solution lump caustic tri sodium phosphate soda ash and resin. Then sulphuric acid in 10 to 15 per cent solution used in pickling the iron. This solution gives off fumes which at times become very dense like a vapor and the workers feel that they have some effect on their lungs and stomach. Please omit name.

M D Pennsylvania

ANSWER.—In this situation it is probable that the sulphuric acid constitutes more of a practical hazard to systemic disease than any of the other agents specified. Sulphuric acid has the reputation of not evaporating, but, as a result of the countless numbers of bubbles produced in the chemical processes of metal pickling, much sulphuric acid may be thrust into the atmosphere of the plating or pickling room. These acid vapors are the source of irritation in the mouth, respiratory tract and along the gastro-intestinal tract. Gastritis and ulcers of the gastro-intestinal tract are believed to be of higher frequency among plating workers, galvanizers and picklers than is true for the general work population.

Second in importance is the sodium cyanide, which, however, is not so highly toxic as has long been the belief of both the medical profession and the public. Chronic poisoning by cyanogen compounds has been questioned but by others it has been associated with nausea, loss of appetite, gastro-intestinal dysfunctions and albuminuria. Acute and severe poisoning by cyanogen gases constitutes a definite disease entity characterized by impaired respiration, marked slowing of the heart rate, lowering of temperature, dilatation of the pupils and quick loss of consciousness, associated with cyanosis of the skin. In spite of extensive applications of cyanides in industry, cases of industrial poisoning are quite rare. On this account greater significance is attached to the sulphuric acid as a more likely source of abnormalities among the workers in this copper plating department.

SEX OF FIRST BORN BABIES

To the Editor—Are there statistics as to which sex predominates among first born babies? If there are no statistics what is the accepted opinion of the best informed physicians?

COL. ONZ C. NICHOLS, Hollywood Calif

ANSWER.—There is some difference of opinion among statisticians regarding the predominance of male children in first births, but the majority seem to think that the number of boys born to primiparas is larger than in subsequent labors. Bidder (*Influence of Age on Sex of Child, Ztschr f Geburtsh u Gynäk*, 1878) said that more boys than girls are born to primiparas.

Pun. ex. (Sex Determination in Man, *Proc Cambridge Phil Soc* 1915) said the same thing.

Siegel (*Schwankungen der weiblichen Fruchtbarkeit*, Berlin, Springer 1917) found that primiparas have 1117 boys to 100 girls and multiparas 104 boys to 100 girls.

H. D. King (*Studies on Inbreeding, J Exper Zool* 1918) found that primiparous white rats had 1159 males against 1011 subsequently.

Halban-Seitz (1824), in a long discussion of the subject, with much literature cited, shows that during and after the Franco-Prussian War there was no increase in boys but, after the Great War there was a demonstrable increase in their number in Germany, so that the notion that nature tries to replace the soldiers lost in war may have some slight basis in fact.

TOXICITY OF SODIUM THIOCYANATE

To the Editor—I have had a patient on sodium sulphocyanate for about eight months. At the present time he is taking about 3 grains (0.2 Gm) every third day. He has an essential hypertension. He feels fine. The urine is normal on bimonthly examination. Is there any danger from the continued use of the drug? Please omit name.

M D Ohio

ANSWER—The usual therapeutic dose of sodium thiocyanate is from 0.5 to 1 Gm daily, in divided doses. Thus there should be no fear of intoxication from the administration of but 0.2 Gm every third day. It is distinctly dangerous to continue medication of 1 Gm daily, for the drug is slowly eliminated and cumulative effects may occur. Renal functional impairment adds greatly to the risk. The tolerance to thiocyanate salts is not uniform, in certain susceptible individuals even small amounts have been known to induce serious intoxication. In the present instance, however, there appears to be no intolerance and no appreciable renal functional impairment. Therefore continued medication with such conservative doses should be without danger.

The earliest symptoms of thiocyanate intoxication are muscular weakness, dermatitis, nausea and vomiting. With more severe intoxication slight fever, mental confusion and disorientation, delirium, convulsive seizures and coma appear in the order mentioned. The present consensus is that thiocyanate is an active vasodilator but that as a rule clinically effective doses often prove too toxic to be considered safe in hypertensive arterial disease. The query does not state whether the small amounts administered have been adequate to reduce the arterial tension and/or keep it depressed. If these amounts have proved efficacious, there appears to be a wide margin of safety in the regimen as stated.

FINGER PUNCTURE METHOD FOR SEDIMENTATION TEST

To the Editor—Have you Cutler's A Finger Puncture Method for Blood Sedimentation Tests on hand or any material on sedimentation tests?

JOHN F. CAREY, M.D., Joliet, Ill.

ANSWER—The Cutler finger puncture method for determining the sedimentation time of erythrocytes is performed as follows:

Carefully cleanse the distal phalanx of one of the fingers with alcohol, and then rub to induce hyperemia. Puncture on the palmar surface. Collect blood in the collecting tube until about half filled (0.5 cc). The tube must be clean and dry. It is filled with 3 per cent sodium citrate solution and emptied. The citrate solution clinging to the walls is sufficient to prevent clotting. From time to time the finger tip and rim of the tube must be wiped with the citrate solution to remove clotted particles, and the tube shaken. If clotting occurs the test must be repeated.

Shake the tube containing the blood to insure uniform distribution of the blood cells. Then draw blood into the sedimentation pipet. (The tubes and pipets may be obtained from the A. H. Thomas Company, Philadelphia.) The blood is drawn up to the zero mark and then kept there by attaching a spring cap to the bottom of the pipet. Place the pipet in the sedimentation rack and determine the change in velocity by observing the upper level of the column of red blood cells every five minutes for one hour. These observations are recorded on sedimentation charts. Thus a graph is traced which shows the position of the blood cell column at any period during the first hour. This technic is described in Kolmer and Boerner's *Approved Laboratory Technic*, New York, D. Appleton & Co., 1931.

TIGHT SPHINCTER ANI

To the Editor—I find that many patients who complain of constipation and flatulence have an overdeveloped and tight sphincter ani. Is forcible dilation or division under general anesthesia the procedure of choice or will the rubber or glass dilator sets accomplish the purpose in these cases? Please omit name if published.

M D California

ANSWER—An abnormally tight sphincter ani accounts for a certain number of cases of constipation and flatulence. There is another group of cases in which the mucosa in the region of the anal sphincter is inflamed and infected. The heightened irritability in this region seems to increase the normal tendency to a reversal of the gradient of forces in this part of the bowel as a result, gas and fecal material tend to remain in the region of the splenic flexure.

In a number of cases a cure can be worked by the proctologist who will carefully dilate the sphincter under anesthesia. Obviously judgment and experience are required in order not to do too much injury to the muscle fibers.

It seems probable that some relief can be obtained at times with the hard rubber dilators or with the two-bladed apparatus that can be inserted by the patient and then opened up with a screw. At least, some patients state that they have obtained relief through their own efforts at dilation.

In many cases the tight anus appears to be a manifestation or end result of an abnormally tense nervous state, and then one must fear a return of the trouble, even after the most successful operative dilation.

RECURRENT CONJUNCTIVITIS

To the Editor—A man aged 34 since June 1932 has had a bloodshot eye with associated conjunctivitis three or four times a year. An attack comes in one eye and the succeeding attack in the other eye. The condition starts subjectively as an irritation and the eye is bloodshot in four or five hours from the onset of symptoms. In the morning he notices that his eye is stuck shut with a yellowish discharge not noticed during the day at the time of an attack. His eyes are somewhat red after he has taken liquor in excess. None of the attacks have been preceded by the taking of liquor. They never affect the sight or the iris. The condition usually lasts from five days to a week. The present attack has lasted a week and a half. The patient saw an eye specialist about a year ago who said that he had slight astigmatism and gave him glasses. There is no fever or systemic disturbance at the time of an attack. A culture of the discharge from the eye showed on gram staining gram positive bacilli probably diphtheroids and a few gram positive cocci. A culture on Loeffler blood agar yielded micrococci. The patient is in good health, is married and has one normal child. He has worked in a filling station for the past two years.

M D Minnesota

ANSWER—It would appear that the patient suffers from spasmodic attacks of an acute purulent conjunctivitis, evidently of bacterial origin. The attacks are naturally self limited but the conjunctiva does not become free from organisms. It would be well to cleanse the conjunctiva with a bactericidal solution (including washing of the tear sacs) until no further organisms can be found on culture.

MECHANISM OF RELIEF OF PAIN IN ANGINA PECTORIS AFTER TOTAL ABLATION OF THYROID

To the Editor—A local physician who is the victim of angina pectoris has requested me to inquire as to the authenticity of a statement that he has seen recently in the medical literature to the effect that the total ablation of the thyroid gland for angina pectoris is of value only as it cuts the sympathetic nerve to the coronary artery. Can you tell me the source of this statement and what is your opinion on the matter?

F. H. HAGAMAN, M.D., Jackson, Miss.

ANSWER—In a recent publication (*Am. J. M. Sc.* 187:753 [June] 1934) evidence was presented by Weinstein, Davis, Berlin and Blumgart indicating that early relief of pain in a patient with angina pectoris, after total ablation of the normal thyroid gland, was due to the section of nerves during the operation. The more lasting relief of the pain was not thought to be due to the section of these nerves but rather to the diminution of the work of the heart when the basal metabolism gradually fell. The whole question is still somewhat in doubt, and in addition to the foregoing two factors there may be a further effect, namely a diminished sensitivity of the heart to epinephrine that follows the total ablation of the thyroid gland.

SINUS IN GUMS AFTER TRAUMA FROM TOOTHPICK

To the Editor—A man aged 37 while picking his teeth about two years ago ran a splinter from the toothpick into the mucous membrane just posterior to the incisor teeth. He thought he removed the splinter at the time but about two weeks following this the area became swollen and tender and a drainage started which lasted for about one month. He was then symptom free for about one year when again the area became swollen and tender and began to drain. The drainage has continued since that time and the last three weeks has become bloody in character. The patient came to me about a week ago. Examination at that time revealed a small sinus or hole about one-fourth inch posterior to the two incisors in the midline. There is no swelling or tenderness in the area and the soft tissues appear to be normal. By using a fine needle it is possible to probe the sinus which seems to extend into the maxillary bone for approximately one-fourth inch. The patient has no other complaints and examination is essentially negative except for this condition. I am enclosing a roentgenogram which will not need to be returned. I would appreciate any suggestions for diagnosis and treatment which you may give. Please omit name.

M D Nebraska

ANSWER—The case in question shows no gross bone change and one would naturally assume that the trouble is due to the toothpick, which, of course, would not show in the roentgenogram. The facts can easily be determined by raising a mucoperiosteal flap in the anterior portion of the hard palate, which will expose the territory involved. In this way the tract can be explored to its complete depth and whatever is present may be easily removed.

DYE OR LEATHER SENSITIVITY

To the Editor—Kindly inform me regarding the treatment of dermatitis due to black leather dye. I have a patient who bought a black leather strap for a wrist watch. Soon after she started to wear it her wrist became inflamed just where it was in contact with the strap. This has spread in the course of a week to a band about 4 inches wide. There is a small area about an inch in diameter on the other wrist. The inflamed skin is slightly elevated and is bright red and itches intensely. Please omit name if this letter is published.

M D Ohio

ANSWER.—The case described presents two main possibilities in diagnosis. One is that the dermatitis is due to dye sensitivity (or possibly even to leather sensitivity), as the inquirer suggests. The other possibility is that it is due to a ringworm (*Trichophyton*) infection secondary to mechanical irritation. The inflamed skin should be examined carefully for signs of fungus infections, and microscopic examinations of the scrapings made. If it is decided that it is not a fungus infection the further question of etiology could be determined by patch tests. It would appear that the most practical procedure would be to discard the leather strap and to treat the inflamed area with mild lotions and protective ointments.

This case recalls to mind the importance of dyes as irritants, especially in dye industries. In a recent bulletin issued by the U S Public Health Service (*Skin Hazards in American Industry*, Public Health Bulletin 215, October 1934) attention is called to the occurrence of dermatitis in dye manufacturing. Some 400 instances of dye dermatitis are analyzed. The authors conclude also that desensitization is not successful in these chronic cases.

USE OF PERTUSSIS VACCINE

To the Editor—In the use of Sauer's pertussis vaccine for immunization it is recommended that an equal amount be injected in each deltoid region and that each subsequent injection be given in a different site. Would you please explain why the full dosage of an injection say 2 cc should be divided 1 cc in each arm instead of 2 cc in one site, and also why a different site should be used at each subsequent injection? It seems unnecessary to make two injections when one would suffice.

M D Long Island

ANSWER.—This vaccine, used for the prevention of whooping cough, not infrequently causes a transient local reaction. It is used early in life—chiefly between the sixth month and the third year. Its particulate nature (10,000 million bacilli per cubic centimeter) is conducive to slow absorption, and the endotoxin of the vaccine often acts on the subcutaneous capillaries, so that a local induration of the skin or a subcutaneous nodule may often be palpated for a week or more. The intensity of these reactions is reduced when the three doses are given bilaterally, a different site being used for each of the weekly injections. If a 26 gage needle is used, there is scarcely any pain.

ASTHMA FROM SENSITIVITY TO COLD

To the Editor—A woman aged 40 whose general health is good and in whom the Wassermann reaction is negative apparently has an allergy to snow storms and snow. Snowstorms immediately precipitate or bring on severe asthma and air hunger. The patient becomes cyanotic. These attacks are relieved by hypodermic injections of epinephrine, atropine and morphine followed by ephedrine and amylal by mouth. I do not understand why snow precipitates these attacks unless the snowflakes bring down with them pollens or other foreign substances in the air. Do you consider it possible to determine the etiology by the use of capillary tubes? Can the patient be immunized to prevent these attacks? Please omit name.

M D Wisconsin

ANSWER.—This is a typical history of asthma caused by sensitiveness to cold. It can probably be relieved by careful alternation of heat followed by ice rubs, covering a limited area of skin. A discussion of the treatment may be found in an article entitled 'Treatment of Physical Allergy,' by W W Duke (*J Allergy* 3 408 [May] 1932).

CANCER IN ESKIMOS AND CHINESE

To the Editor—Have you any data on the incidence of cancer in general as the cause of death in the Chinese of the interior of China or of the Eskimos in their native state as compared with ours?

HANS SCROEDER M D New Orleans.

ANSWER.—No accurate data on cancer as a cause of death in the Chinese or the Eskimos are available because there are no census reports to show the population, and also no death certificates to show with any accuracy the cause of death in any given district. Physicians working in hospitals in Chinese cities report that they see many cases of cancer among the Chinese, and in a paper by Fibiger (*Ztschr f Krebsforsch* 20 148 [June] 1923), who studied the records of physicians

and hospitals in Greenland, it is shown that cancer was about as proportionally frequent in those Eskimos who came to the institutions as in a similar population elsewhere.

PHENOLPHTHALEIN WITHOUT EFFECT ON BLOOD FORMING ORGANS

To the Editor—Kindly let me know whether phenolphthalein has any effect on the blood stream or blood producing organs. Do you know of a case of agranulocytic angina or neutropenia caused by phenolphthalein?

M D, Texas

ANSWER.—Phenolphthalein has no known effect on the blood stream or the blood forming organs. No case of agranulocytic angina or neutropenia due to phenolphthalein is on record.

BURNS FROM PERMANENT WAVE MACHINE

To the Editor—In *Queries and Minor Notes* in *THE JOURNAL*, July 20 page 223 a question is asked with regard to the treatment of scalp burns from permanent wave machines. The questioner aptly states that these are becoming more frequent since a constantly larger number of women are facilitating the dressing of their more or less unruly hair with the fixation which permanent waving produces.

In undertaking to treat burns resulting from this process, one must take two things into consideration: first that usually the burns are deep (third degree) and, second, that they are frequently infected from the ever present bacteria on the scalp and hair. It is the infection that at times causes considerable trouble not only because it retards healing but because it is not infrequent to find a persistent furunculosis as a sequela on the neck and back or other parts of the body.

The routine that I carry out in treating these patients is as follows:

- 1 The area surrounding the burn is washed well with soap and water.
- 2 An adequate area is shaved around the burn.
- 3 A corrosive mercuric chloride (1:3000) compress is applied and left in place for fifteen minutes every twelve hours.
- 4 Débris is removed without causing bleeding.
- 5 The burn is dressed with a piece of gauze that has been saturated with an aqueous solution of tannic acid 5 per cent. This gauze is held in place with hairpins.
- 6 If the posterior cervical glands are affected (and this is very frequent) and the patient shows any systemic reaction (fever, leukocytosis) she is put to bed. Ice caps are placed over the inflamed cervical lymph nodes for thirty minutes at intervals of an hour.
- 7 If furunculosis develops the patient is treated with an antogenous vaccine.

LESTER HOLLANDER M D Pittsburgh

DIAGNOSIS OF APPENDICITIS

To the Editor—From the list of signs under 'Diagnosis of Appendicitis' (*THE JOURNAL* July 13, p 139) the following were omitted:

- 1 Britton's sign (*Ann Int Med*) Retraction of the right testicle while moderate pressure is made over an inflamed appendix denotes gangrene of the appendix. Retraction of the testicle is not present in the absence of gangrene and disappears after rupture of the appendix.
- 2 Hyperextension of the right thigh with leg extended and patient lying on left side. This is a modification of Cope's extension test which combines with it the mesentery pull sign of Ott.
- 3 Tap on heel. With the patient supine and the legs extended but relaxed a moderately vigorous tap on the patient's right heel will produce pain while a similar tap on the left heel does not.
- 4 Leukocytosis. The white count may be high, low or normal in any stage of appendicitis contrary to the opinion held by many surgeons.
- 5 Temperature. This is as variable as leukocytosis and sometimes as misleading when given too much consideration.
- 6 Localization of tenderness by barium sulphate enema. This increases pain by increase of pressure within the bowel and also allows palpation under fluoroscopic control.

I venture to submit these additions to an already extensive list believing that they come within the definition of Sign, 'any objective evidence of disease.'

RICHARD B STOUT M D Elkhart Ind

EFFECTS OF BELLADONNA ON CHILD

To the Editor—Regarding Effects of Belladonna on Child (*Queries and Minor Notes THE JOURNAL* July 6 p 67) may I call attention to the remarkable fact that children and especially infants are frequently but little affected by belladonna. I have seen a man atropinized by 10 minims (0.6 cc) of tincture of belladonna while his son of 8 years was not affected by the same dose.

In the pylorospasm and habitual vomiting of infants Haas uses from $\frac{1}{30}$ to $\frac{1}{15}$ grain (13 to 2.5 mg) of atropine sulphate daily and has employed up to $\frac{1}{10}$ grain (4 mg). Ochsensins gave $\frac{1}{15}$ grain (0.76 mg) daily to an infant four weeks old and $\frac{1}{30}$ grain (13 mg) to one of 3 weeks. Lundbergh gave up to $\frac{1}{30}$ grain (65 mg) daily to a child of 8 months. These men report no serious untoward effects.

On the other hand Munns, White, Brennenman and others report poisoning in infants from single doses of $\frac{1}{1000}$ to $\frac{1}{500}$ grain (0.06 to 0.04 mg) or from several such doses.

Six minims (0.36 cc.) of tincture of belladonna contains $\frac{1}{40}$ grain (0.12 mg) of total alkaloids equivalent in action approximately to $\frac{1}{40}$ grain (0.13 mg.) of atropine sulphate.

Kansas June Report

Dr C. H. Ewing, secretary, Kansas State Board of Medical Registration and Examination, reports the written examination held in Topeka, June 18-19, 1935. The examination covered 10 subjects and included 100 questions. An average of 75 per cent was required to pass. Eighty three candidates were examined, all of whom passed. Twelve physicians were licensed by reciprocity and 3 physicians were licensed by endorsement. The following schools were represented:

Book Notices

Practical Endocrinology. Symptoms and Treatment. By Max A. Goldzicher M.D. Endocrinologist Gouverneur Hospital New York. Cloth Price \$5. Pp 326 with 41 illustrations. New York & London D Appleton Century Company Inc 1935

The author presents what appears at first sight to be a plausible discussion of present knowledge of endocrinology applied to clinical medicine. The work is well arranged and fairly well written. However, much of the material does not withstand critical analysis. Many conditions are described as having an endocrinologic etiology for which there is little except a theoretical basis and often not a good theoretical basis at that. Despite this fact, the casual reader may not be aware of the extent to which pure conjecture has served as source material for this book.

The author states, for instance, that the 'function [of the parathyroid glands] with respect to calcium metabolism has been definitely established.' This will be news to the physiologists, the fact that some of the effects of parathyroid extracts on calcium distribution in tissues and body fluids are known does not constitute adequate basis for the foregoing statement. Five hormones are listed as having been 'isolated' from the anterior pituitary. "Isolation" implies separation in pure form, actually, not one of the pituitary principles has yet been obtained in a pure state. The distribution of pigment is said to be under the control of intermedin. Zondek and Krohn have shown that the extract of the pars intermedia of the pituitary, which they call intermedin, is capable of causing the expansion of chromatophores in certain species thus intermedin may control the "distribution" of pigment within the range of expansion of a single chromatophore but not in any other sense, so far as present knowledge goes. The reader is told further that growth of hair and its distribution on the body surface responds to stimulation by the anterior lobe of the pituitary. The role of the pituitary in this respect belongs in the realm of conjecture, the studies so far made on this subject are no more than suggestive.

The author claims that most of the epinephrine entering the blood stream from the adrenals is in the form of "a complex compound which is physiologically inert," it reverts to activity and becomes demonstrable only after separation from its lipid fraction." No evidence is presented for this improbable statement. Perfusion of the frog leg or rabbit ear is presented as a sensitive biologic assay method for epinephrine. Neither of these test objects is suitable for assay, as has repeatedly been demonstrated, the intestinal segment method, which is much superior, is not mentioned. Epinephrine is stated to be the physiological antagonist of insulin", this claim is certainly not supported by adequate evidence. Epinephrine, according to the author, "is looked upon as a general activator of physiological processes and a stimulator of practically all metabolic activities." This too will be important news to the physiologists. If epinephrine does all this, why bother with the other hormones to which the author has devoted the major portion of the book?

The author apparently considers that he is the discoverer of the adrenal cortical hormone, although he has never presented adequate evidence that his extract will support the lives of adrenalectomized animals beyond the maximum survival period of control animals, and the announcement of Rogoff and Stewart supported by convincing evidence, preceded his report by well over a year. The discussion of the physiology of the adrenal cortical hormone is open to severe criticism, but space does not permit detailed consideration of this section. The reader is told that choline becomes a decisive factor in the physiological peristalsis of the intestinal tract." For this statement also there is no adequate evidence.

Thus far this review has been concerned only with the preliminary section on physiology, the remainder of the book is devoted to clinical applications of this dubious information. The ease with which in many cases the author classifies the various syndromes on the basis of a single (alleged) essential glandular disturbance must be amazing to any one acquainted with the complexities of glandular interrelationships. Yet the discussions are written with such easy dogmatism as to take the reader unawares. Detailed consideration of all this material is not feasible, to those sufficiently versed in the rudiments of endocrinology to separate the reasonable from the improbable, some of the material in the section devoted to diagnosis may be useful for reference, to others it cannot be recommended. The nomenclature of the active principles of various glands and of commercial products is confused throughout the book. It is alarming, from the standpoint of rational therapeutics, to note the nature of some of the commercial preparations recommended by the author for clinical use.

The author views with some skepticism, but nevertheless with tolerance, the highly reprehensible practice of subtotal resection or denervation of the adrenals for alleged hyperfunction of these organs in the absence of actual tumor. This practice, in view of the serious hazards to life (or, if the patient survives, to health) and the small likelihood, if any, of therapeutic benefit, deserves condemnation.

Lehrbuch der Krankenernährung. Herausgegeben von Prof. Dr. C. R. Schlayer und Dr. J. Prüfer. Teil 1. Allgemeine und spezielle Diätetik. Bearbeitet von Chefarzt Dr. H. Deicher und anderen. Teil 2. Rezeptensammlung. Von Dr. J. Prüfer und anderen. Cloth. Price 8 marks each. Pp 250 with 3 illustrations. 308. Berlin and Vienna. Urban & Schwarzenberg 1935.

This textbook, written by nine authors, consists of two parts, the first dealing with general and special dietetics, the second composed of recipes and sample menus. As the practical side of the subject forms the scope of the book, theoretical considerations, familiarizing the reader with the underlying principles of scientific dietetics, have been limited to a minimum. Due consideration has been given to the principle of certain flexibility and adaptability of standard diets to individual needs. The first part of the first volume offers a concise review of the physiology of nutrition and of the composition of common food-stuffs. It also describes the general technic of preparation of meals and discusses the problem of organization of diet kitchens in hospitals and clinics. The second part of this volume is devoted to a general discussion of diets indicated in various pathologic conditions such as obesity, undernourishment, diabetes, gastro-intestinal diseases and arthritis. The second

volume also is composed of two parts the first furnishes a detailed composition of the diet under discussion, while the second consists of sample menus and cooking recipes, describing in detail various modes of preparation of meals. The book is highly practical both in plan and in treatment, and its splendid organization makes complete information readily available. Its greatest field of usefulness will probably be among dietitians, but the general practitioner will also find it useful. The only drawback from the standpoint of the American reader is a profusion of recipes not well known or popular in this country.

Physical Chemistry for Students of Biology and Medicine. By David Ingersoll Hitchcock Ph.D. Associate Professor of Physiology in the Yale University School of Medicine (With Laboratory Directions.) Second edition. Cloth. Price \$2.75. Pp. 214 with 28 illustrations. Springfield, Ill. & Baltimore: Charles C. Thomas, 1934.

This book covers the material that has been offered to medical and graduate students at Yale University for some years as a part of the work in physiology. After presenting the most fundamental aspects on the properties of gases and the laws covering them, the author follows with the logical application of these laws to liquids and solutions. In this connection, emphasis is placed on the law of mass action in solutions, the consideration of hydrogen ions, and the theories underlying the indicator and electrometric methods for the pH estimation. Adsorption and the colloidal state are treated briefly but included are membrane potentials and equilibria. A clear and brief chapter on gas equilibria in blood is followed by chapters on kinetics of enzyme action, oxidation-reduction potentials, and the transformation of energy. The new edition includes instructions for twelve laboratory experiments involving the application of the osmotic pressure to cell volume hemolysis and to colloidal solutions and the relations to pH and freezing points, indicator methods for pH estimation, experiments on the iso electric point, cataphoresis, enzyme activity, and reaction velocity. The book is well organized. The references are arranged conveniently and the more prominent authors are honored with brief biographic footnotes. Each chapter closes with a number of problems intended for the application of the principles discussed. The book is stimulating, although probably too difficult and 'too chemical' from the point of view of the majority of medical students. This valuable book might have been made more attractive to the medical student if the application of the science had been emphasized more frequently.

Epidemics and Crowd Diseases. An Introduction to the Study of Epidemiology. By Major Greenwood D.Sc. FRCP. FRS. President of the Royal Statistical Society. Cloth. Price \$5.50. Pp. 409 with 8 illustrations. New York: Macmillan Company, 1935.

This book, by one of the most distinguished English epidemiologists of our day, will be warmly welcomed by American students, who have already had a foretaste of its quality in the three Herter lectures delivered by Greenwood at Johns Hopkins University in 1931 and published in 1932. In the present volume 134 pages is devoted to general principles and methods and the remainder to special illustrations. The statistical method of treating epidemiologic data is emphasized throughout, but most of the book can be read easily and with pleasure by one not versed in the higher mathematics.

The author is refreshingly outspoken on fundamental epidemiologic problems. "We do not really know why the rate of mortality for tuberculosis has fallen as it has, we have not the least idea why scarlet fever, deadly fifty years ago, is now a relatively trivial cause of mortality" (p. 65). "Without doubt, it is idle to speak of the conquest of tuberculosis" (p. 360).

We are entitled to infer that for the scarlet fever of our generation isolation cannot be shown to have conferred any advantage in the way either of prevention of infection or of reducing mortality (p. 222). The subject of experimental epidemiology is condensed into ten pages to satisfy, as the author humorously explains, his sense of proportion. There is a particularly fine chapter on the artificial immunization of man which discusses some of the difficulties encountered in interpreting the results of inoculating large groups of the population. Three chapters on the influence respectively of nutritional, occupational and psychologic factors—which the author

prefers to call procatastic rather than predisposing causes—should be read by all sociologists. The author's point of view is shown by the following (p. 126).

More than seventy years ago Walter Bagelhot in a criticism of Charles Dickens made this comment:

He began by describing really removable evils in a style which would induce all persons however insensible to remove them if they could be has ended by describing the natural evils and hereditary pains of the present state of being in such a manner as must lead to excite discontent and repining. The result is aggravated because Mr. Dickens never ceases to hint that these evils are removable though he does not say by what means. Nothing is easier than to show the evils of anything Mr. Dickens has not infrequently spoken and what is worse he has taught a great number of parrot like imitators to speak in what really is if they knew it a tone of objection to the necessary constitution of human society."

These parrot like imitators have multiplied enormously in the last seventy years and their parrot like insistence upon research into this or that evil of modern life is sometimes a serious obstacle to real research because having no conception of the complexity of the problem of inter related group factors and a simple faith in the doctrine that what is not recorded did not happen they are apt to believe that some particular evil (noise for instance) is both easily remediable and quite new.

In the section on special illustrations, some readers will consider that a disproportionate amount of space (one fourth) is devoted to smallpox, but much can be forgiven for the sake of the amusing chapter on Edward Jenner and Charles Creighton. It is a little surprising to find typhus treated exclusively as a louse-borne disease and to read the statement that the United States "first experienced the disease" cerebrospinal fever in the period 1854-1875 (p. 311). The author's style is clear and readable and only three misprints have been noticed (pp. 42, 47, 317). One rubs one's eyes, however, to find the locution "facts published by Topley and I" (p. 313).

Verlaufsformen der Erkrankungen des Respirationssystems. Mit Anschluss der Tuberkulose. Von Prof. H. von Hoesslin Direktor der Inneren Abteilung des Oskar Ziehen Krankenhauses in Berlin-Lichtenberg. Boards. Price 4.20 marks. Pp. 150. Leipzig: Georg Thieme, 1935.

Professor von Hoesslin presents in this volume the various nontuberculous diseases of the respiratory system. A good discussion is presented on the etiology of acute and chronic bronchitis as well as the treatment of these conditions. Considerable space is given to the diagnosis of bronchial asthma, its cause in each case being sought. The types of bronchiectasis are presented with reference to etiology. In treatment, collapse therapy is given consideration and attention is called to the fact that it is not always possible to bring the disease under control in this manner. The use of neosphenamine is discussed. Tumors of the lung and pulmonary syphilis are emphasized. Throughout the book, cases are cited to illustrate various points in diagnosis and treatment. There are no illustrations and no bibliography.

An Essay on the External Use of Water. By Tobias Smollett. Edited, with introduction and notes by Claude E. Jones. Reprinted from Bulletin of the Institute of the History of Medicine Vol. III No. 1 January 1935. Boards. Price \$1. Pp. 82 with portrait. Baltimore: Johns Hopkins Press, 1935.

In his introduction to this eighteenth century classic in balneology, the editor points out that in Smollett's literary works there is a clear picture of contemporary medicine. Although he took a medical degree (in 1750), served his professional apprenticeship at Glasgow, was warranted surgeon's second mate in the British navy, and cultivated throughout life the friendship of physicians, he devoted himself to literature almost exclusively soon after receiving his medical degree. The adventures of his heroes, and his biographic vignettes, roguish satire and searching observations, are all much concerned with the state of medicine in his time. His comments on medicine include such items as the conduct of medical examinations, the grades in the professional hierarchy and the jealousies existing among their constituents, the dependence on blood letting for any and all of multitudinous ailments, the physical ordeals that try the mettle of the country practitioner, the growing distrust in medication, the avaricious and pretentious charlatan, who will scramble up two pairs of steps for a fee of six lives and who has 'cured many parties that were never diseased' the life of the surgeon's apprentice, who was little more than slave to a pecunious master and the pompous trumpery of doctors who practiced at English spas—fellows bungling in practice but equipped with all the silly accoutrements of the trade. These features and many others are presented in the editor's introduc-

tion, as well as quotations from the adventures of Peregrine Pickle, Roderick Random, Launcelot Greaves and Humphry Clinker

Interest in mineral waters during the eighteenth century was widespread. Smollett ventured into medical writing to improve his reputation. He not only followed a popular trend but discussed a mode of treatment from which he had received great benefit. Smollett's terminology is not that of his distinguished but misdirected predecessors, yet with their concepts his own have much in common. Thus, scrophulous and scorbutic ulcers are cured 'by the aspersion of common well-water,' its pressure 'supports the weakened sides of the capillaries.' The most unyielding tumor may be cured 'by letting warm water fall from a high place, *guttatim*, or drop by drop upon the parts.' The warm bath, Smollett claims, renders the rigid fibers of our body more pliable and washes away the acrid impurities lodged therein. As an habitue of the spa, and protagonist of bathing, Smollett pleads for reform in the management and sanitary arrangements of English baths, he would have the occupants sheltered from inclement weather and diseased persons segregated, and the *bagno* made architecturally pleasant. Smollett would have these salutary springs "the gift of heaven," fully protected, and their usefulness extended.

The volume is attractively bound and contains the portrait of Smollett by Nathaniel Dance. The editor's commentary is supported by references and textual notes. Students of medical history will find it a welcome addition to their libraries.

Konstitution und Tuberkulose im Kindesalter. Von Dr. Kurt Klare. Ärztlicher Direktor der Prinzregent Luitpold Kinderheilstätte Scheidegg. Paper. Price 4 marks. Pp 43 with 32 illustrations. Leipzig: Georg Thieme 1935.

This is an excellent discussion of the relationship of constitutional type to the development of tuberculosis in children. The specialist in tuberculosis now feels that the onset, type and course of a case of tuberculosis are markedly influenced not only by the infection and milieu but also by the constitutional factors. The constitution of an individual consists of a number of influences such as habitus, physiologic properties, reactions, heredity and psyche. Of all these the reaction to various stimuli, exogenous and endogenous, is most important. Two types of children are described: the hypersensitive exudative-lymphatic, and the hyposensitive asthenic type. These are discussed with case illustrations. The booklet should interest physicians engaged in the care of tuberculous children.

Community Hygiene. By Dean Franklin Smiley A.B. M.D. Medical Adviser and Professor of Hygiene in Cornell University and Adrian Gordon Gould Ph.B. M.D. Assistant Medical Adviser and Assistant Professor of Hygiene in Cornell University. Second edition. Cloth. Price \$2. Pp 369 with 91 illustrations. New York: Macmillan Company 1935.

This is a revised edition of a work originally published in 1929. In it, certain statistics have been substituted for old ones, some new material has been added, and old material rearranged. Those portions dealing with the problem of the cost of medical care and its causes have been rewritten. A discussion of the recent experience of Chicago in tracing an epidemic of amebic dysentery to defective plumbing is included. The book, in general, presents facts concerning the promotion and safeguarding of public health that are felt to be essential to the mental equipment of every college man and woman. It should make a useful textbook for the teaching of community hygiene.

Docteur Charles J. Finlay. Son centenaire (1933) sa découverte (1881). Par le Professeur Francisco Dominguez, membre d'honneur de l'Académie des sciences médicales de la Havane. Paper. Pp 302 with 8 illustrations. Paris: Librairie Louis Arnette 1935.

Written on the centenary of Finlay's birth, this biography is a sympathetic study of the man and a vigorous statement of the belief that Finlay was the real discoverer of the essential part played by the mosquito in the transmission of yellow fever. Not only does the author give credit to Finlay for originating the hypothesis but he holds that there is abundant evidence that Finlay did actual experimental transmissions of the disease as early as 1881 by mosquitoes that were unquestionably *Aedes aegypti*. Considerable space is given to the elucidation of the exact accomplishments of the American commission headed by

Dr. Walter Reed. The early works of Beaupertuy are extensively quoted and discussed, with the result that much of the glamor usually thrown around this writer is dispersed. This book will be of great value especially to students of tropical medicine and of medical history.

The Woman Asks the Doctor. By Emil Novak M.D. F.A.C.S. Associate in Gynecology Johns Hopkins Medical School. Cloth. Price \$1.50. Pp 189 with 11 illustrations. Baltimore: Williams & Wilkins Company 1935.

The author set out to write a book in such a way as to talk collectively to many women in the manner in which every physician often talks to one woman in his office. The aim has been carried out admirably, as was to be expected because of the author's extensive experience as a gynecologist. As he says, there is not a single subject discussed in the book which he has not many times explained to individual women in his consulting room. Among the chapters are some devoted to superstition and folk lore of menstruation, the cause and significance of menstruation, the glands as related to female functions, puberty, the menopause, the hygiene of pregnancy, the "safe period," sterility, leukorrhea, cancer and the sex life of women. The author does not say much about the sex life because he thinks that this subject is an individual problem which should not be discussed in a popular book. The book is written in a fascinating style with many personal touches. It should be recommended to every female, young and old, for it contains an enormous amount of useful information. Furthermore it will add to the happiness of many women who think they are inferior for one reason or another and it will induce many negligent women to seek medical advice.

A Review of Certain Aspects of a Recently Recognized Disease of the Blood (Agranulocytosis or Agranulecytic Aegria). By E. W. Adams. O.B.E. M.D. Ministry of Health Reports on Public Health and Medical Subjects No. 76. Paper. Price, 6d. Pp 21. London: His Majesty's Stationery Office 1935.

This pamphlet consists of a brief review of the entire question of agranulocytosis, including history, nomenclature, clinical observations, etiology, prognosis, diagnosis and treatment. It was prepared by the author for official use of the Ministry of Health of Great Britain. No new material is presented, but an impartial and accurate summation of the disease is made with particular reference to some of the more controversial questions, such as etiology and methods of treatment. The author accepts the amido-pyrene etiology of many cases of the disease. He deplores the confusion in terminology. Based on his review of the literature, he believes that pentnucleotide therapy is the best available. He states the total number of cases in Great Britain as twenty-two. An interesting record of one recovered patient is presented, showing the profound fall in granulocytes following the administration of a single dose of amido-pyrene. This publication probably represents a general summation of opinions concerning agranulocytosis in Great Britain.

Objective and Experimental Psychiatry. By D. Ewen Cameron M.B. Ch.B. D.P.M. Physician in Charge Reception Service Provincial Mental Hospital Brandon Manitoba. Cloth. Price \$3. Pp 271. New York: Macmillan Company 1935.

This constitutes a brief treatise on many of the most modern concepts regarding psychiatric diseases. It is written clearly and therefore is easy to comprehend. It discusses in a detailed manner experimentation and quantitation in general in relation to psychiatric and psychologic problems. The book also suggests constructive criticisms of its own thought. There is a chapter discussing the adequacy and inadequacy of the tests of intelligence. Introversion and extraversion, word association tests, conditioned reflexes and heredity are discussed concisely. A chapter on statistics has for its conclusion that its chief value is in clarifying classifications and in promoting suggestions. Blood sugar tests, ephedrine and epinephrine, basal metabolism and blood pressure studies in relation to various mental diseases are amply discussed. There is a chapter on sedimentation rate, the hemato-encephalic barrier and its relations to personality. There is a chapter on the pathology of schizophrenia, manic-depressive insanity, epilepsy, senile psychosis, arteriosclerotic psychosis, dementia paralytica and mental deficiency, with a brief review of encephalographic studies in mental diseases. There is an excellent bibliography appended after each chapter which makes the book desirable for all interested in neuropsychiatry.

Medicolegal

Assault and Battery Unlawful Practice of Medicine as Constituting—Lexchin consulted the defendant osteopath relative to a swelling on his right leg near the ankle. The osteopath punctured the swelling. Later the patient consulted other physicians and was taken to a hospital, where his ailment was diagnosed as leukemia, myelogenous type. The patient ultimately died. The plaintiff as administratrix of his estate sued the osteopath. The declaration, in one count, charged the defendant with malpractice, and, in a second count, with assault and battery, based on the contention that the osteopath, in puncturing the swelling, unlawfully practiced surgery. The trial court gave judgment for the osteopath on both counts and the plaintiff appealed to the Supreme Court of Michigan.

There was no evidence of negligence or unskilful treatment, hence the charge of malpractice was not established. With respect to the charge of assault and battery, said the court, the act of the defendant osteopath in puncturing the swelling bore no causal relation to the death of the patient. Furthermore, the court said, the count for assault and battery in puncturing the swelling "fell flat" because the patient consented to the puncture. The plaintiff contended, however, that the consent was given under a misunderstanding of the defendant's right to perform such a surgical operation and, therefore, was void. The liability of the defendant, the court pointed out, for assault and battery cannot be predicated alone on the violation, if any, of a license law, regardless of whether he possessed and exercised the skill and care ordinarily possessed and exercised by surgeons in the community. The court found no occasion to decide whether an osteopath, duly licensed as such, may practice surgery in Michigan, but did observe that the puncturing of the swelling to relieve pressure could hardly constitute a surgical operation. The judgment of the trial court for the defendant was affirmed.—*Lexchin v Mathews (Mich)*, 256 N W 825

Dental Practice Acts Dentistry Not Divisible into Professional and Business Departments—The dental practice act of Wisconsin authorizes the state board of dental examiners on its own motion to make investigations and conduct hearings "in regard to the action of any licensed dentist and dental hygienist or any person who it has reason to believe is acting or has acted in such capacity within the state." Acting under this authority, the board served notices on Painless Parrmer, Inc., and A. J. Rust, a stockholder of that corporation, ordering them to appear before the board on a certain day "to give evidence." Rust and the corporation sought to restrain the board from holding the hearing, and from an adverse decision of the trial court they appealed to the Supreme Court of Wisconsin.

The constitutionality of reasonable regulations over the dental profession has been upheld said the court. The creation of the state board of dental examiners and the conferring on them of the power of investigation and of holding hearings in certain matters specified in the statute are well within the constitutional requirements of an effective law. The legislature may enact legislation designed to accomplish the regulation of matters properly within the legislative field and may authorize an administrative commission, within valid limits, to provide rules and regulations for the administration and enforcement of the law within its expressed general purpose. This includes the right to conduct investigations and hold hearings pertinent to such purpose. The dental practice act in authorizing the board to hold hearings and to subpoena witnesses violated no constitutional rights of the plaintiffs.

The plaintiffs contended, however, that the board was without jurisdiction to hold the proposed hearing because neither of them was licensed to practice dentistry. The fact that the plaintiffs do not actually engage in the performance of dental operations is not controlling, said the court. The law contemplates regulation of the profession to such an extent as to protect the public not only against the unprofessional conduct of licensed dentists but also against other persons who, by management or some other intimate relation, are in charge of those who are practicing dentistry under a single management.

The method of operating a dental corporation, the securing of patients desiring dental treatment by licensed dentists, is a proper subject of regulation under a system which recognizes the practice as a profession. The contract for the dental work is consummated between the plaintiffs and the patient, the advertising by the corporation is also the act of the plaintiffs and in this manner they are holding themselves out as licensed dentists. In the case of *Painless Parker v Board* 216 Calif. 285, 14 P (2d) 67, the court, in answer to the contention that there is a distinction between the practice of dentistry and the purely business side of the practice, stated:

The law does not assume to divide the practice of dentistry into that kind of departments. Either one may extend into the domain of the other in respects that would make such a division impractical if not impossible. The subject is treated as a whole. If the contention of appellant be sound then the proprietor of the business may be guilty of gross misconduct in its management and violate all standards which a licensed dentist would be required to respect and stand immune from any regulatory supervision whatsoever. His employee, the licensed dentist would also be immune from discipline upon the ground that he was but a mere employee and was not responsible for his employer's misconduct whether the employer be a corporation or a natural person. On grounds of public policy such a condition could not be countenanced.

No one would dispute the right of any person to own a dental office equipment. The question most appropriate here is whether the thing owned is used for a given purpose by a person lawfully entitled to use it. Ownership is not the absolute test of the right of use.

The notices that were sent to the plaintiffs, said the court, were lacking in fulness of detail and contained no careful statement of the charges, if any, which the board had under consideration. This fact, however, constitutes no warrant for the granting of injunctive relief. If and when the plaintiffs are accused of violating the provisions of the dental practice act, they will be afforded the opportunity of demanding a proper complaint in that proceeding.

The Supreme Court therefore affirmed the order of the trial court which, in effect, dismissed the action instituted by the plaintiffs.—*Rust v State Board of Dental Examiners of Wis* (Wis) 256 N W 919

COMING MEETINGS

American Academy of Ophthalmology and Otolaryngology Cincinnati, Sept. 14-20. Dr. William P. Wherry 107 South 14th Street, Omaha, Executive Secretary.
American Association of Obstetricians Gynecologists and Abdominal Surgeons Sky Top Pa. Sept. 16-18. Dr. James R. Bloss 418 Eleventh Street, Huntington, W. Va. Acting Secretary.
American Congress of Physical Therapy, Kansas City Mo. Sept. 9-12. Dr. Nathan H. Palmer 921 Canal Street New Orleans, Secretary.
American Hospital Association, St. Louis Sept. 30-Oct. 4. Dr. Bert W. Caldwell 18 East Division Street, Chicago Executive Secretary.
American Public Health Association Milwaukee, Oct. 7-10. Dr. Reginald M. Atwater 50 West 50th Street New York, Executive Secretary.
American Roentgen Ray Society Atlantic City, N. J. Sept. 24-27. Dr. E. P. Pendergrass 3400 Spruce Street Philadelphia Secretary.
Association of Military Surgeons of the United States New York Oct. 3-5. Dr. H. L. Gilchrist Army Medical Museum Washington D. C., Secretary.
Colorado State Medical Society Estes Park September 5-7. Mr. Harvey T. Sethman 537 Republic Building Denver Executive Secretary.
Delaware Medical Society of Wilmington Oct. 8-9. Dr. William H. Speer 917 Washington Street Wilmington Secretary.
Indiana State Medical Association Gary Oct. 8-10. Mr. T. A. Hendricks 23 East Ohio Street Indianapolis Executive Secretary.
Kansas City Southwest Clinical Society Kansas City Mo. Oct. 10-12. Dr. Ralph R. Coffey 1103 Grand Avenue Kansas City Mo. Secretary.
Kentucky State Medical Association Louisville Sept. 30-Oct. 3. Dr. A. T. McCormack 532 West Main Street, Louisville Secretary.
Michigan State Medical Society Sault Ste. Marie, Sept. 23-25. Dr. Burton R. Corbus 313 Metz Building Grand Rapids Acting Secretary.
Mississippi Valley Conference on Tuberculosis Madison Wis., Sept. 12-14. Mr. A. W. Jones 613 Locust Street, St. Louis Secretary.
Ohio State Medical Association Cincinnati, Oct. 2-4. Mr. C. S. Nelson, Hartman Theatre Building Columbus Executive Secretary.
Oregon State Medical Society Gearhart, Sept. 19-21. Dr. Blair Holcomb, Stevens Building Portland Secretary.
Pennsylvania Medical Society of the State of Harrisburg Sept. 30-Oct. 3. Dr. Walter F. Donaldson 500 Penn Avenue, Pittsburgh, Secretary.
Southern Minnesota Medical Association Austin Aug. 25-26. Dr. Harold C. Haben 102 Second Avenue SW Rochester Secretary.
Utah State Medical Association, Logan, September 5-7. Dr. George A. Curtis Judge Building Salt Lake City Secretary.
Virginia Medical Society of Norfolk, Oct. 15-17. Miss A. V. Edwards 1200 East Clay Street, Richmond, Secretary.
Wisconsin State Medical Society of Milwaukee Sept. 1-20. Mr. J. C. Crownhart 119 East Washington Avenue Madison Secretary.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to *THE JOURNAL* in continental United States and Canada for a period of three days. Periodicals are available from 1925 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

- Treatment of Hemorrhage Caused by Peptic Ulcer. G. A. Hendon, Louisville, Ky—p 255
- Factors Pertinent to Reduction of Mortality in Cholecystectomy. M. Behrend, Philadelphia—p 258

Intestinal Tuberculosis—Granet believes that tuberculous enteritis is a common disease and is present in most patients with advanced pulmonary tuberculosis. In an attempt to delimit criteria that would facilitate early diagnosis and better therapeutic results, 2,086 tuberculous patients were studied clinically and pathologically. This study was limited to moderately advanced and advanced nontoxic patients with pulmonary tuberculosis. Roentgenoscopy of the gastro-intestinal tract revealed lesions in 37 per cent. Postmortem check up showed a relatively high degree of accuracy for this method of diagnosis. A history of gastro-intestinal symptoms was found to be unreliable as a diagnostic aid, as symptoms were absent in the majority of positive enteritis cases. Furthermore, the proportion of patients complaining of gastro intestinal symptoms was only slightly greater in the positive enteritis group than in the negative patients. A study of the sputum showed tubercle bacilli in practically all positive enteritis cases. Similarly necropsy revealed pulmonary cavities in almost all fatal cases of enteritis. Sigmoidoscopy revealed rectal involvement in only two of 150 patients examined.

Estimation of Enzyme Concentration in Duodenal Fluids—Lueders describes methods for the determination of trypsin, lipase and amylase in duodenal fluids. The modification by Hollander of his previous methods for the estimation of tryptic and lipolytic activity has proved of distinct value during the last four years of its application. The test for amylase, with but slight modification has proved satisfactory during the last fifteen years. The author states that any clinician trained in the Lyon technic of nonsurgical duodenal drainage should find the methods described simple, rapid and sufficiently accurate. As soon as some such practical procedure for the estimation of pancreatic enzymes in duodenal fluids has been widely accepted as reliable, it may well give fresh impetus to further investigation of secretory dysfunction and diseases of the pancreas. It should also prove a valuable routine addition to the diagnostic survey of patients with any disease involving the gastro-intestinal tract as well as those with disorders of

nutrition, digestion and assimilation. Occasionally, normal values for enzyme concentration were found in one or more of the duodenal fractions of the diseased group, but it was rare to obtain normal concentration of the three enzymes as in the normal groups. In each of five cases of diabetes the pancreatic amylase was low in amount, and in every extraction of duodenal fluid.

New Concept of Mènière's Disease—Foldes says that there seems to be a striking similarity in the pathogenesis of Mènière's disease to epilepsy, eclampsia of pregnancy, eclampsia of infancy, migraine, angina pectoris, bronchial asthma, the allergic diseases and gout. These diseases manifest themselves in the form of attacks which appear to be due to a retention of water and minerals that is local and temporary, rather than generalized and continuous. The attacks cease when the retained liquids disappear from the respective organ. For the treatment of this group of diseases an antiretentional therapy has been developed which employs a diet based on the recognition of the fact that all food elements, such as proteins, carbohydrates, fats, water, minerals and vitamins, influence the water and mineral metabolism. The author found that, while the antiretentional diet in itself, or together with the administration of phenobarbital, is ineffective, the addition of quinine sulphate, phenobarbital and the extract of *nux vomica* to this diet, the protein content of which is slightly lowered, is followed by a complete disappearance of the attacks within a few days with no relapses observed thus far. A complete abolition of the attacks such as he observed in his four cases can hardly be ascribed to the medication in itself. The results observed, he believes, are not attributable to the administration of quinine sulphate by itself but to the concerted action of quinine sulphate and the diet.

Carbohydrate Metabolism in Hypothyroidism Induced by Thyroidectomy—Rudy and his collaborators cite a case of severe uncontrollable diabetes mellitus complicated by tuberculosis of the lungs, in which total ablation of the thyroid was performed. Before operation, the basal metabolic rate was +7 per cent and the patient showed no evidence of hyperthyroidism. The extirpated thyroid tissue was found normal on gross and microscopic examination. The diabetic condition, which could not be adequately controlled prior to operation under optimal conditions with diet and an average insulin dosage of 95 units daily, was readily controlled by diet and 44 units of insulin daily after hypothyroidism developed. A level of hypothyroid

ism at which the patient remained free from any unpleasant symptoms of myxedema was maintained by small doses of thyroid. The authors suggest that the treatment of hypothyroidism with small doses of thyroid as applied in this patient may be useful also in some patients with diabetes and spontaneous myxedema. As evidence that the reduction in insulin requirements in their patient was due to the hypothyroid state, they found that the administration of thyroid sufficient to restore the preoperative metabolic level resulted in relapse of the patient's diabetic condition to the preoperative status. Total thyroidectomy is not advised in the treatment of diabetes mellitus except in the rare case of severe diabetes that cannot be controlled adequately by the application of all known therapeutic measures.

Heterophile Antibody Test in Leukemia—Weinstein and Fitz-Hugh found the heterophile antibody titer in the serums of sixteen cases of leukemia to be uniformly and repeatedly at a low level (zone 1) regardless of the stage and type of the disease. One case of acute myelogenous leukemia was found to be in zone 2. The patient, however, had received twenty-eight blood transfusions. This constant finding may be of value in ruling out the diagnosis of leukemia in any case in which a high heterophile antibody titer is found. A low or normal titer of heterophile antibody was found also in three cases of Hodgkins disease, five of lymphosarcoma, five of polycythemia vera, four of agranulocytic angina and a number of miscellaneous cases including typhoid simple adenitis, syphilis, tuberculosis and anemia. A high titer (zone 3) was found in serum sickness and acute infectious mononucleosis, thus confirming the reports of Paul, Bunnell, Davidsohn and others. The parenteral administration of horse serum did not produce a rise in the heterophile antibody titer in five cases of chronic lymphatic leukemia. This is in accord with previous evidence. A similar failure of increase of heterophile antibody titer following horse serum injections was found in one case of 'atypical' Hodgkins disease and in two of lymphosarcoma, suggesting the possibility of a biologic relationship of these conditions to lymphatic leukemia. The parenteral administration of horse serum in three cases of chronic myelogenous leukemia produced a marked rise in heterophile antibody titer similar to that occurring in nonleukemic individuals. This is not in accord with previous evidence and suggests the possibility of a real biologic difference between myelogenous leukemia on the one hand and the lymphatic group on the other.

Blood Transfusion in Treatment of Obstetric Hemorrhage—According to Dieckmann and Daily, obstetric hemorrhage is responsible for more than 10 per cent of the maternal deaths. The mortality has not decreased in the last twenty years despite the use of blood transfusions. The mortality rate from obstetric hemorrhage can be lowered only if sufficient blood is transfused to raise and maintain the hemoglobin to approximately 10 Gm per hundred cubic centimeters of blood. The transfusion must be adequate in amount and must be given within a short time after the hemorrhage. Further transfusions may be given within a period of hours or spread over several days, depending on the amount of blood required and the clinical condition of the patient.

Treatment of Eclampsia—Bryant treated 121 cases of eclampsia as follows. From 5 to 15 minims (0.3 to 1 cc.) of an extract of veratrum viride is given hypodermically immediately after the first convulsion. This is repeated as often as is necessary to keep the pulse below 80 or the blood pressure at least 20 mm below the convulsive level. The usual case requires from one to three doses at intervals of from ten to fifteen minutes, then doses every one, two or three hours until the patient is well over the acute stage. Oral administration of slightly larger doses of from 10 to 20 minims (0.6 to 1.3 cc.) may replace the hypodermic injections as the patient recovers. From 10 to 20 cc of a 50 per cent solution of magnesium sulphate is given by deep injection immediately following the first dose of veratrum. This is repeated in smaller doses of from 2 to 5 cc. every six hours, three times a day, and twice a day on successive days as the acute attack subsides. From one-half to 1 ounce (15 to 30 cc.) of saturated solution of magnesium sulphate is given by mouth twice a day. Fluids are forced by mouth as soon as the patient is conscious. In the meantime from 2,000 to 3,000 cc of physiologic solution of sodium chloride is given by hypodermoclysis if the patient is over the convulsive stage but still comatose. Intravenous injection of from 100 to 500 cc. of from 5 to 50 per cent dextrose is frequently used. Alkalies are given by mouth to conscious patients in doses of from 60 to 120 grains (4 to 8 Gm.) from three to six times a day. Fruit juices well sweetened, are administered at frequent intervals. A low protein diet, consisting chiefly of fruit juices, vegetables and bread, is allowed as soon as the patient feels hungry and is apparently in no immediate danger of convulsions. Chloral, bromides or one of the barbiturates is given in appropriate doses to those patients who become restless during recovery from the acute stage. Ether is used sparingly at the time of delivery. In the antepartum case, no attempt is made to induce labor until the patient is well over the acute stage or shows marked resistance to treatment. In the patient who responds to treatment, labor is induced from twenty-four to seventy two hours after the acute attack has subsided. In this series there were seventy-one patients with convulsions before delivery. The usual precautions are used during the convulsions. The patient is not restrained during a convulsion, except so far as is needed to

prevent self injury by falling. No anesthetic is used for the control of the convulsions. In three cases magnesium sulphate solution was injected intraspinally. Two patients received magnesium sulphate solution intravenously. The effect of the hypodermic injection of a therapeutic dose of veratrum viride is startling. The blood pressure falls rapidly, sometimes going as low as 50 systolic. This marked fall is transitory but is followed by a more or less prolonged period during which the pressure is well below the original level. The heartbeat is slowed to 40 per minute in some patients but soon picks up and remains at from 60 to 80 until the effect of the drug has worn off. The pulse rate usually follows the blood pressure level fairly closely. Atropine or morphine or both are antidotes for veratrum viride. Vomiting is an early effect. The degree of vomiting varies with the individual susceptibility of the patient. The respiration is always slowed considerably but never to such a degree as to be harmful. The individual susceptibility to the drug is very marked and for this reason treatment cannot be absolutely standardized. In the author's cases, convulsions occurred before delivery in seventy-one. Of fifty postpartum patients, twenty-three delivered and had convulsions before admission. The total number of maternal deaths was twelve. Of the patients 60 per cent had no convulsions after treatment was started, 15.8 per cent had only one convulsion and 24.2 per cent had more than one convulsion.

Treatment of Elusive Ulcer of Bladder—Sears treated four female patients for elusive ulcer of the bladder with the following technic. Ten per cent cocaine is applied to the urethra for five minutes. The bladder is emptied by catheter, the patient placed in the correct knee chest posture, the vaginal orifice opened to allow air to enter the vagina, and a Kelly cystoscope introduced into the bladder. The lesion is located and studied, and, after aspiration of all the urine from the bladder vertex, is thoroughly swabbed with pure phenol. If any of the solution touches the normal mucosa it is immediately neutralized by an applicator saturated with alcohol. After the ulcer is thoroughly painted the patient remains in the knee-chest posture with the cystoscope in place for a few seconds until the action of the phenol has taken place. As the cystoscope is withdrawn if the trigon and urethra are inflamed, they are painted with 10 and 5 per cent silver nitrate respectively. The air is then allowed to escape and the patient to go about as usual. There is often some increased discomfort for a few days about which the patient should be warned. The lesion is inspected in two weeks and may or may not require more treatment. In all cases thorough swabbing of the ulcer caused but little distress and no complications and was followed by prompt and prolonged relief.

Treatment of Gonorrhea in Women—Notes describes the clinical treatment of 2129 positive cases of gonorrhea of the female genitalia over a period of four years. Positive diagnosis was based on smears with gram-negative intracellular diplococci having the morphology of the gonococcus combined with objective clinical signs. Extracellular gram-negative diplococci were considered suggestive. Each patient was observed two months for recurrence of positive smears. The basis of treatment in the beginning was drainage and antisepsis. In 1931 the antiseptics used in treatment included iodine and compound solution of cresol as douches and by topical applications, and of 384 cases admitted four were discharged. In 1932 the antiseptics used included iodine, compound solution of cresol, mercurochrome and 10 per cent silver nitrate and of 522 patients admitted eighteen were discharged. In 1933 of 546 cases admitted forty-eight were discharged. In August 1933 treatment on the bases of creation of local reaction and drainage with the omission of antiseptics was begun as follows. All cervixes with cervical glands functioning were cauterized one or more times with the electrocautery at intervals of two or more months in order to cause local reaction and to give better drainage of the active focus. The urethral meatus and the cervix were treated weekly with applicators saturated with 25 per cent solution of silver nitrate. Five per cent sodium bicarbonate douches were taken by the patient at home twice daily. Nightly instillations of 1 drachm (4 cc.) of 1 per cent lactic acid jelly were made by nozzle to the vaginal vault in order to promote the normal bacterial flora

and to get rid of secondary invaders, which cause desquamative vaginitis. During the first six months of this period, clinical improvement and increase in negative smears were marked. The author concludes that antiseptics should be abandoned in the treatment of gonorrhea in women.

Postoperative Pulmonary Atelectasis—Snyder states that it is generally agreed that the determining factor in the production of pulmonary atelectasis is bronchial obstruction by mucus. All conditions that tend to reduce the vital capacity of the lung, or tend to increase the amount or viscosity of bronchial mucus, or hinder its expulsion, predispose to pulmonary atelectasis. In a typical case of severe, massive atelectasis the onset occurs within forty-eight hours of operation. The symptomatology consists in sudden elevation in temperature, pulse and respiratory rate, dyspnea, cyanosis, coughing and severe pain in the chest or in the abdomen. Expansion of the chest is limited or absent over the affected area. Percussion will establish the position of the heart borders displaced to the side of the lesion. Early there is often hyperresonance over the affected lung, but as the bronchioles and alveoli become filled with secretion dullness will be found. At first the breath sounds are absent or diminished and there are no rales but as air again gains access there may be tubular or amphoric breathing and moist crackling or bubbling rales. In the course of a few minutes to many days the lung expands, the heart returns to normal position and breath sounds can be heard over the affected lung with many moist rales. Most cases of pulmonary atelectasis are generally less severe and are not recognized unless the chest is thoroughly studied daily, or twice daily following operation. In severe cases the roentgen observations are elevation of the diaphragm on the affected side, narrowing of the chest on that side, increased obliquity of the ribs, narrowing of intercostal spaces, a displacement of the trachea, heart and mediastinum to the affected side and a variable amount of shadow in the affected lung area. Early there may be little or no increase in density over the lung, later the shadow may be dense and homogeneous. Roentgen examination is not always essential in the diagnosis and treatment of this condition. The author refers to eleven patients four of whom had heart disease. Two patients in the group had syphilis. In seven of the cases atelectasis developed within

the first thirty-six hours. There were three cases following appendectomy, three following cholecystectomy, two following cesarean section, two following hemorrhaphy and one following amputation through the thigh. There were two deaths. The two patients who died had heart disease and a mitral lesion. Local and spinal anesthesia do not decrease the incidence of pulmonary atelectasis. Large doses of morphine and other sedatives before and after operation should be avoided. The operating time should be as brief as possible. Carbon dioxide, 10 per cent and oxygen should be administered at intervals during all spinal anesthetics to avoid acapnia, for five minutes at the end of all local and general anesthetics and for five minutes, three or four times daily, for at least forty-eight hours following all abdominal operations. The patient's position should be changed every three or four hours after operation. Deep breathing at frequent intervals should be encouraged. Dilatation of the stomach should be avoided by using the nasal tube at the first indication of gastric distention. The author's cases were treated by the postural method of Sante. This consists in rolling the patient back and forth on the uninvolved side. Percussion over the involved lung facilitates the expulsion of mucus. The patient is not left in this position for long, as atelectasis may then develop in the other lung. Carbon dioxide and oxygen induce deeper breathing and probably a widening of the lumens of the bronchi and bronchioles. They should be employed only in conjunction with the postural method of treatment. If they are administered with the patient lying on the affected side, it may lead to firmer incarceration of the obstructing mucus.

Ganglionectomy for Hyperhidrosis—Pearl and Shapiro state that conditions of sweating which interfere with the health, occupation and peace of mind or the continued happy existence of an individual justify surgical intervention. Sympathetic ganglionectomy at the proper level will produce a total inhibition of sweating in the desired regions. When anhidrosis is produced, vasomotor paralysis occurs in the identical areas of distribution, as evidenced by a rise of surface temperature. It is impossible to influence separately the fibers for sweating and those for vasoconstriction by surgical means. The accompanying release of normal vasoconstriction gives no uncomfortable symptoms. The authors report a case in which a woman, aged 22, obtained complete relief from excessive sweating following sympathetic ganglionectomy and trunk resection. The left inferior cervical and first, second and third thoracic sympathetic ganglions were exposed by a posterior muscle splitting approach and freed of all connecting branches, and the trunk was removed from above the inferior cervical to below the third thoracic ganglion. There was an immediate rise of surface temperature of the left upper extremity to the normal vasodilatation level and a complete absence of sweating of the left upper extremity and the homolateral half of the head, face and upper part of the thorax, anteriorly and posteriorly. The rise of surface temperature and the absence of sweating persisted in the areas affected until fourteen months after operation. The amount of perspiration of the unaffected regions was greater than before operation. The delineation of areas of anhidrosis was obtained by the application of external heat. Four months after operation cervicodorsal ganglionectomy, ramisection and trunk resection were carried out on the right side to the same extent as on the left. Fourteen months after the first operation, and ten months after the second operation, there has been no perceptible evidence of sweating even after long exposure to external heat.

Splanchnic Nerve Section in Juvenile Diabetes—De Takáts describes a supradiaphragmatic retropleural approach to the splanchnic nerves. With the patient in a semilateral position, a paravertebral incision is made, four fingerbreadths from the midline starting at the level of the angle of the scapula and curving laterally over the tenth intercostal space for a distance of from 5 to 6 cm. The incision transects the long muscles of the back and exposes the tenth and eleventh ribs, which are subperiosteally resected for a length of about 6 cm, the midline being approached as close as possible. To facilitate the approach to the lateral surface of the vertebrae, the intercostal vessels are doubly ligated and cut. The intercostal nerves may be preserved but may also be transected without any harm. The distal stump of the tenth nerve is

transected with a fine suture of black silk and wrapped in a moist gauze compress. The endothoracic fascia, which covers the pleura, is carefully incised and dissected away from the pleura throughout the length of the incision. After the pleura has been stripped away from the proximal stumps of the ribs, the remaining proximal stump and some of the transverse process are removed. The pleura is gently stripped until the thoracic sympathetic trunk appears surrounded by loose connective tissue and fat. The trunk may be identified by the bulbous swelling of its ganglions. On dissection of the pleura farther forward the major splanchnic nerve appears, showing multiple connections with the sympathetic chain. After procaine hydrochloride anesthesia, the thoracic chain and the splanchnic nerve are excised. To prevent regeneration of the major splanchnic nerve, the proximal stump of the nerve is implanted into the distal stump of the tenth intercostal nerve. After complete hemostasis, the pleura is allowed to fall back in place, the muscles are carefully sutured and the skin is closed. No drainage is left in the wound. The operation has been performed by the author so far three times, the patients being young persons with diabetes. An adequate dextrose and fluid intake, which is essential in any operation for diabetes, is carefully maintained. A dextrose solution of 5 per cent is given in a subcutaneous drip, 1,000 cc. in about five hours, which may be started during the operation, and another thousand cubic centimeters in the afternoon. About 2,000 cc. of a 5 per cent dextrose solution will supply 100 Gm of sugar. Another thousand cubic centimeters of Ringer's solution is given during the night, thus furnishing 3,000 cc of fluids during twenty-four hours. Of the author's three cases, only the third is regarded as a thorough test of the value of the operation because of improper selection in one instance and partial technical fault in the second. In the third case a decrease of 50 units of insulin a day was accomplished. A final evaluation of results with respect to the diabetic state of the patients who were operated on is to be made.

Fractures of Bodies of Vertebrae—Speed states that the main mechanism of fracture of the corpus vertebrae is compression. If no flexion accompanies compression, the body is crushed and lessened in height uniformly, the posterior border in lateral view being reduced equally with the anterior border. The corpus tends to broaden laterally and may be separated into two or more fragments, one of which may push back into the canal to compress the cord, while the other may be displaced forward as far as it can go under the restraint of the anterior spinal ligament. If flexion forward and compression act together, a wedge-shaped piece, varying from the size of a pea to nearly the whole anterior portion of the body, is broken off from the anterior superior border of the corpus, the plane of separation extending diagonally down and forward. The main portion of the body, especially the posterior, retains its height or diameter and the spinal canal is protected by the intact posterior longitudinal ligament, while the anterior height is diminished with accompanying displacement forward of the whole spinal segment above. When compression is accompanied by lateral flexion, the amount of comminution may be increased, one side of the body is crushed down more than the opposite side, and displacement laterally into subluxation may be found. The body breaks into fragments easily through its weaker center, the seat of venous sinusoids. Other adjacent bodies may suffer similarly. The first roentgenologic study must compare bodies immediately adjacent above and below the injured segment to search for breaking down of the bone density, suggesting impaction of the cancellous tissue into itself. Later changes in bone density indicate aseptic necrosis or, if accompanied by new bone formation, may require two to four months for roentgenographic demonstration and depend on the amount of blood extravasation at the time of injury. The period of immobilization used in treatment and the secondary postural changes in the spine. All types of reduction by means of hyperextension with any required lateral flexion may be followed by plaster-of-paris dressings. Each fracture of the vertebral body should be studied roentgenologically before reduction to determine whether it was caused by pure compression in the long axis or by compression flexion with a fragment broken off the superior surface of the body and dis-

placed forward and downward. The third class of combined flexion and compression with lateral displacement may be recognized often by graver cord pressure symptoms. If the fracture is the result of compression flexion with a relatively small fragment broken off the upper anterior border of the body, reduction by hyperextension by Jones's method or on a spinal bed that may be rapidly elevated into hyperextension at the site of fracture, followed by an ambulatory plaster-of-paris torso jacket for ten to fourteen weeks, is sufficient treatment. For patients who have sustained great compression with broadening or lateral gross displacement and uniform loss of height of the corpus, reduction by hyperextension plus traction in the long axis of the body is required in most cases. This is best done on a spinal bed with traction on head and feet. A plaster bed or torso corset embracing the thighs may be used, depending on the amount of dislocation laterally. The patients should be kept supine on the plaster for from eight to fourteen weeks. Later they may be fitted with a plaster-of-paris corset or back brace, which is worn until roentgenologic demonstration of healed bone trabeculae has been made.

Excretion of Mercury After Injections.—Sollmann and his collaborators studied the excretion of mercury after the injection of various mercuric compounds and compared the injection method with the oral and inunction methods. They found that the antisiphilitic efficiency of mercurial treatment appears to be conditioned by the continued maintenance of an adequate concentration of diffusible, dissociable mercury. The mercury that is fixed and stored in the tissues does not appear to have therapeutic significance. The urinary excretion of mercury serves as an indicator of the diffusible mercury. The fecal excretion is unimportant, qualitatively and quantitatively, except for injections of flumerin. The urinary curve for excretion ranges from periodic, with the injection of the diffusible organic compounds, to continuously cumulative, with methods employing the less soluble compounds that form absorption depots, including inunctions, oral administration and intramuscular injections of slowly soluble or precipitant compounds. All the effective antisiphilitic methods show the continuously cumulative type of excretion. In accordance with this the closest correlation exists between the antisiphilitic efficiency and the level for daily urinary excretion toward the end of the treatment (the end of the fourth week). All forms of treatment yielding levels below 0.5 mg of mercury daily at the end of the fourth week are clinically ineffective. These include the inunctions with ointments of mild mercurous chloride and with weak (5 per cent) ointments of metallic mercury and mercury oleate, the oral administration of mercuric chloride in doses of 15 mg daily, the intravenous injections of oxycyanide and the intramuscular injections of the benzoate in the usual dosage, intermittent intramuscular injections of red mercuric iodide and intravenous injections of compounds with their mercury in firm organic combination—salirgan, novasurol and mercurosol. These give very high temporary levels for excretion of mercury but they sink to insignificant ones within a few hours. All methods of treatment that secure a daily urinary excretion of from 0.8 to

1 mg of mercury at the end of the fourth week are effectively antisiphilitic and may cause stomatitis. The ordinary and the massive inunctions, the daily oral administration of 0.2 Gm of mercury with chalk, the daily intramuscular injection of mercuric sodium bromide and the weekly intramuscular injection of mercuric oil come within this group. With the last preparation there is the constant danger of cumulative intermittent absorption and intoxication. The oral administration of yellow mercurous iodide and mercuric sodium bromide, 0.5 Gm daily, and some of the methods of injection raise the level for the fourth week to 2 or 4.5 mg of mercury daily. These higher levels probably act more rapidly against syphilis, but they are also more likely to produce severe stomatitis, which limits their continuance and reduces their efficiency. Considerable quantities of mercury are retained in the tissues indefinitely even with the intravenous injections of diffusible organic compounds (from 31 to 77 per cent). These retentions are especially high with the colloidal solutions (from 96 to 99 per cent). Since the antisiphilitic action ceases promptly with the excretion, this retained mercury is therapeutically useless. It is undesirable since it may be harmful to the tissues.

Cervicodorsal Sympathectomy in Multiple Sclerosis.—Wetherell resorted to cervicodorsal sympathectomy as a measure of relief in eight cases of multiple sclerosis. The operation consists of removing the inferior cervical and the first thoracic ganglion by the posterior approach. The transverse process of the first thoracic vertebra and about 1 inch of the first rib are removed. The ganglions are picked up and the cords above and below are sectioned as are all the rami, and the structures thus sectioned are removed. With the exception of the first case, bilateral sympathectomy was done in one stage. General anesthesia with nitrous oxide and ether was used. All patients had little postoperative discomfort and stood the procedure exceptionally well. An attempt is made to rationalize the procedure on a basis of betterment of cerebral circulation which may relieve irritation and allow a more normal blood supply and more normal conduction of nerve impulses.

- *Simple Conception of Dementia Praecox. C. S. Bluemel. Denver—p. 540.

Dementia Praecox.—Bluemel states that it is not inconceivable that emotional stress may produce a toxic state which in the case of a biologically deficient organism leads to degeneration of the brain cortex. Following such a line of reasoning one would implicate the endocrines as a source of

intermediate disturbance. One would suspect the gonads for the reason that the psychosis commonly occurs in the reproductive period of life. The end result of dementia praecox can be identified as organic change in the brain cells. It is probable that damage to the brain cells, and especially the dendrites, accounts for the associational defect that characterizes the fully developed psychosis. Presumably there occurs a sort of physiologic short circuiting, which breaks the former associational pathways. It is logical to suppose that cellular dysfunction accounts also for the so-called somatic hallucinations. The toxic theory of dementia praecox explains not only the degeneration of the brain cells in the later stages of the disease but also the phenomenon of recovery without defect during the early stages of the psychosis. Apparently the toxic condition may abate in any stage of the disease. The resultant damage is proportionate to the duration and violence of the destructive process. With early arrest of dementia praecox there is absence of sequels, and the patient seems to have suffered nothing more critical than a transient toxic confusional psychosis. With delayed arrest there are inevitable sequels.

Leukocytosis Produced by Artificial Fever—To determine the changes occurring in the number of blood cells during artificial fever treatments, in which the patients' temperature was elevated and maintained at a constant level for a definite period by radiant energy, Cohen and Warren observed ten patients during a total of eleven treatments. There were seven treatments for gonococcal infection, one patient in this group was suffering also from latent syphilis and chronic infectious arthritis. The diagnoses in the remaining four cases were syphilis of the central nervous system, chronic infectious arthritis, brain tumor and carcinomatosis. All observations of temperature during treatment were made by means of a resistance thermometer placed in the rectum of the patient. In practically every case the red blood cell count, hemoglobin, white blood cell count and differential count, including the Schilling hemogram made from coverslip blood smears stained with Wright's stain were determined before treatment and every hour starting when the temperature had reached the desired height and was being maintained at a constant level. These determinations were continued for several hours after the termination of the fever. The blood studies were then followed at intervals until the patient was discharged from the hospital. The counts were made from blood taken from the ear. A leukocytosis was found in every case. The maximal change and the onset, duration and extent of this change, in relation to the period of fever varied from patient to patient.

A relative and absolute increase of polymorphonuclear leukocytes was observed during or immediately following the febrile period. There was a substantial relative and absolute increase in immature polymorphonuclear leukocytes in six of the eleven cases. There was a relative and absolute decrease in lymphocytes in all cases. There was a slight rise in the red blood cell count and hemoglobin during or immediately following the period of fever. Immature red blood cells were found in a single case, which also exhibited the greatest increase (20 per cent) in hemoglobin during a fever of 41.6 C. (106.9 F) for twenty-one hours. These observations suggest a mobilization into the circulation of available and nearly mature cells of the myeloid and erythrocytic series as a result of the fever, while the cells of the lymphoid series decrease during this period.

Value of Takata and Ara Reaction in Cirrhosis of Liver—Ragins employed the Takata-Ara reaction in 276 patients, using the Jezler modification. The clinical diagnosis was used as a basis for classification of the diseases and when ever possible, was substantiated by postmortem examination or surgical biopsy. The cases were classified into fourteen main groups, with cirrhosis of the liver heading the list. That the test is of value in cases of decompensated liver conditions due to cirrhosis is without doubt. For latent liver damage the test is not entirely reliable. The Takata-Ara reaction is positive in 98 per cent of the cases of cirrhosis of the liver. The sim

phlicity with which the test is carried out warrants its use in hospital and office practice as both a diagnostic and prognostic aid in cases of cirrhosis of the liver. Liver impairment occurs in hyperthyroidism, as shown by the Takata-Ara reaction.

Complement Fixation Reactions in Carcinoma—By fractionating according to Lehmann-Facijs the alcoholic extract of cancer tissue, Lundy obtained positive complement fixation reactions in 70 per cent of fifty-one cases of carcinoma examined. Of twenty-eight carcinoma serums tested with the ethylene chloride antigen, 100 per cent were positive. With the cholesterolized phosphatid fraction of the alcoholic extract, all but two of 107 four-plus syphilitic serums reacted positively. With the ethylene chloride fraction of twenty-seven four-plus syphilitic serums tested, eleven were negative. Of ninety-two normal serums one gave positive reactions with the phosphatid fraction, while out of eleven such serums four were positive with the ethylene chloride fraction. The antigen concerned in fixation with cancer serums is not destroyed by heating it to 125 C. but is destroyed by certain alkaline reagents. The cancer antigen apparently is different from the syphilitic antigen, and it appears probable that these two antigens may be separated.

Occlusion of Portal Vein—Boyce and his collaborators present experiments proving that 1. Complete occlusion of the portal vein in one stage, as well as successive occlusion of both branches, is incompatible with life. 2. Occlusion of the main portal trunk in several stages is a feasible procedure if not more than two thirds of the vein is occluded at any one time. Experimental proof is advanced to disprove the theory that the loss of blood into the gastro-intestinal tract is the only cause or the chief cause of death in portal occlusion. The theory is advanced that death in portal occlusion is due (1) to an abrupt and immediate fall in blood pressure, brought about by a neurogenic factor with resulting reflex inhibition, as in primary shock, plus the abrupt diversion of a large amount of blood from the circulation with a resulting decrease in blood volume, and (2) to the maintenance of the blood pressure at this critical level, as the result of a continued gradual withdrawal of blood from the circulation, with a continued gradual decrease in blood volume as the diverted blood is collected in an area from which it cannot escape plus the stagnation of this blood in the gastro-intestinal tract, which has all the effect of primary hemorrhage. Occlusion of the portal vein for pylophlebitis of appendical origin is discussed in its clinical aspects, and it is concluded that the operation although theoretically sound and technically possible, actually has a limited field and always is attended with grave risks.

Hyperparathyroidism and Renal Disease—Albright and Bloomberg state that hyperparathyroidism is such a frequent cause of renal stone formation that its presence must be ruled in or out in every case of this disease. They studied a series of twenty-three proved cases of hyperparathyroidism. Of these fifteen patients had renal calculi and three others renal lesions due to calcium deposits in the intrarenal urinary passageways. Eleven patients were suspected of having the disease only because of the renal calculi and had no bone disease. Only

five patients had bone disease without renal disease. A frequent finding in hyperparathyroidism is the presence of many finely granular casts in the urinary sediment. The granules have been shown to contain calcium, probably calcium phosphate. The casts can be made to change into hyaline casts, as the urine is made more acid by administering ammonium chloride by mouth. Their continuous presence in large numbers is an indication that intrarenal damage is in progress. The factors governing the formation of these casts, which in a way are microscopic calculi in the renal tubules, are probably the same that govern stone formation in hyperparathyroidism. These factors are the concentrations in the urine of calcium, of phosphate and of hydrogen ions. Stone formation in hyperparathyroidism belongs to that etiologic group in which the presupposing abnormal factor is an excess of crystalloids in the urine.

Gonadotropic Hormone in Urine with Tumor of Testis—Hinman and Powell state that the pituitary gland, pregnancy and embryonal tumors are known causes of the appearance in the urine of gonad-stimulating hormones. The stimulation of the growth of gonads and genitals of infantile animals varies with the origin of the hormone producing it, the amount present in the urine and the animal used for the injections. The authors make a qualitative test for as low as 250 units in infantile mice and rats first on fresh unaltered morning urine. If positive, a quantitative test may be made. The microscopic ripening of the graafian follicles is more easily read in mice than in rats. The gross enlargement of the uterine horns is more definite and diagnostic in mice than in rats. At the age of twenty or twenty-one days the ovary of the rat may show open follicles normally. The hydrocele fluid with tumor of the testis may contain more of the hormone than the patient's urine. The majority of tumors of the testis are embryonal. The urine of patients having embryonal tumors contains a substance that produces gross enlargement of the uterine horns or microscopic ripening of ovarian follicles (reaction I of Zondek) when injected into infantile female mice and rats. The presence of such a gonadotropic hormone in the urine of a patient with a tumor of the testis is evidence of testicular malignancy and its absence is evidence against malignancy. The effect of irradiation on the amount of hormone in the urine, as determined by quantitative methods before and after irradiation, gives a good indication of roentgen sensitivity and may be used as a therapeutic test in conjunction with the clinical effect on metastases, when present. The therapeutic test of irradiation must be interpreted in conjunction with the histologic structure of the tumor, the clinical absence of metastases or the character of metastases when present and the physical condition of the patient. The hormone test permits a more accurate prognosis and a better control of therapy than has been possible heretofore.

Diabetes Insipidus After Epidemic Encephalitis—Himler discusses a case in which almost all the symptoms of the so-called neuropituitary syndrome were present: polydipsia, polyuria, obesity, elevated blood pressure, tendency to somnolence, headaches and mild emotional and psychic disturbances. The febrile illness which preceded the onset of the polydipsia

in infancy was undoubtedly an attack of epidemic encephalitis. The subsequent development of parkinsonism and oculogyric crises fourteen years later leaves little doubt that epidemic (lethargic) encephalitis was the sequel. Because of the close proximity of the globus pallidus and substantia nigra to the hypothalamus, it can be readily understood how an inflammatory process in the basal ganglions may by slight extension medially involve the region in which the diencephalic thirst center is located. Various types of medication were tried in an attempt to reduce both the parkinsonian tremor and the excessive desire for fluids. The usual drugs for parkinsonism failed to have an appreciable effect on the intake and output. Solution of pituitary intramuscularly four times a day, and pitressin nasal spray every six hours, were definitely the two most valuable agents in reducing the polydipsia and polyuria. When the intake was kept between 6,000 and 8,000 cc. daily, the patient also felt generally more comfortable. The possibility of a psychogenic element was excluded by substituting sterile hypodermics at the time solution of pituitary was being given, and there was a prompt rise of the intake to the original level within a day. The persistence of symptoms in the patient for nineteen years would indicate that they are in all probability permanent. In this respect the diabetes insipidus bears the same general prognosis as other sequels of epidemic encephalitis. In view of the organic nature of the underlying cause, it is doubtful whether any therapy for the abnormal thirst sensation can be more satisfactory than that for the parkinsonism. What beneficial effect is obtained seems to be due to intermediation of the pituitary. The exact physiologic relationship between the hypophysis and the hypothalamus, and the manner in which it is influenced by the administration of posterior lobe extracts, has not as yet been determined.

Treatment of Acne Vulgaris with Pregnancy Urine Extract.—Lawrence and Feigenbaum treated fifteen patients presenting acne vulgaris with an initial dose of 1 cc of anterior pituitary-like principle (100 rat units) to determine the individual reaction to the extract. The dose was then increased to 2 cc. three times weekly. In only one patient was there enough reaction to make it inadvisable to give the larger dose. The treatment was interrupted three or four days before each menstrual period and resumed from two to four days after menstruation ceased. In no case was there any demonstrable effect on normal menstruation. In patients who had acne and menorrhagia or metrorrhagia, the improvement in the acne paralleled the return of menstruation to normal. This association of effects suggests that, in these patients, the acne and the menstrual disturbance were due to an identical hormone imbalance. Of the authors' patients eight have been cured while four are greatly improved and two show slight improvement. No definite conclusions can be drawn from so small a series of observations but these observations and the natural history of acne suggest that its cause lies in an endocrine imbalance coincident with adolescence consisting possibly in a quantitative or qualitative abnormality of the newly activated gonadal hormones.

Chromoblastomycosis.—Carrión reports a case of chromoblastomycosis in which the infection started more than twenty years ago on the left wrist. The disease has followed a slow and chronic course, gradually but steadily spreading, until now it covers most of the hand, forearm and elbow. It does not show either the nodules or the large, prominent, vegetative tumors usually present in this mycosis, and the lesions are more patchy, psoriasiform, less infiltrated and, in places, more or less papillomatous. The invasion of new regions seems to have taken place chiefly by peripheral extension of old foci. The occurrence of extensive zones of scarred skin indicates that healing has eventually taken place in the older portions of the pathologic areas. The histopathologic changes are indistinguishable from those observed in other cases of chromoblastomycosis. The fungus isolated from the lesions is a hormodendrum, which resembles in some respects Hormodendrum pedrosoi but which shows a considerable number of clean-cut differences clearly separating it from that species. Cultures on Sabouraud's medium are characteristic. The rate of growth is much slower, the gross morphology is markedly different and the consistency is much more brittle than in Hormodendrum pedrosoi. Microscopically the thallus as a whole is darker and the hyphae are coarser and more tortuous. The spore heads are more compact, owing to the sphericity of the conidia, the relatively large diameter of the cross septums which separate them and the frequency with which a spore gives rise to two or more secondary conidia. Finally, the size, shape and mode of articulation of the individual spores are entirely different from Hormodendrum pedrosoi. Because of the compact arrangement of the spores the name Hormodendrum compactum is proposed to designate this species.

Inflammation of Descending Portion of the Duodenum.—Sussman states that duodenal inflammatory lesions occur distal to the duodenal bulb and particularly in the portion between the knee and the papilla major. He studied eight cases in which the diagnosis of inflammatory lesion of the descending portion of the duodenum was made roentgenologically. Operations were performed in two, but the information obtained was not satisfactory and the conclusions arrived at must be evaluated accordingly. The cases could be grouped roentgenologically as stenosis and irritability of the descending portion alone, stenosis with the demonstration of an ulcer crater within the

stenotic lesion, stenotic lesion in association with ulcer of the duodenal bulb, and stenotic lesion in association with gastric ulcer. Noteworthy features were relatively slight to marked narrowing of the lumen of the duodenum between the upper knee and the papilla major, marked irritability, irregularity in outline or unusual smoothness, and a marked disturbance in the longitudinal mucosal folds so that they either disappeared or were irregular in their distribution as demonstrated by compression technic. In some cases an ulcer crater was seen. There was no organic obstruction. There may be an associated peptic ulcer. The clinical symptoms of peptic ulcer are obtained but are exaggerated, often there is stress on nocturnal pain, nausea and vomiting in attacks and poor response to a Sippy regimen. Hyperacidity is a fairly prominent feature. An appeal for careful study of the descending portion of the duodenum is made, particularly in routine cases to determine the normal, and in cases in which there is a suggestive history of ulcer and a lesion is not demonstrated in the stomach or duodenal bulb. The diagnosis of inflammatory disease of the descending portion of the duodenum rather than essential peri-duodenitis appears to be the more satisfactory in these cases.

Modification of Radiation Treatment of Carcinoma of Stomach—Kaplan used the following technic in three patients who had carcinoma of the stomach. It consists in a preliminary gastro-enterostomy, followed by the delivery of the stomach into the abdominal wound, localization of the lesion and implantation of suitably prepared, filtered radon seeds. The number of seeds and the strength of the radon in each varies with the extent of the lesion. From twenty to forty gold seeds were used, containing approximately 1 millicurie of radon in each seed. The seeds were implanted in the part of the stomach wall involved by the tumor and were placed in parallel lines up to, but not puncturing through, the mucosa of the stomach. Seeds were also placed in all palpable accessible lymph nodes in the vicinity of the stomach. The gold filtration of 0.3 mm absorbs approximately 95 per cent of the beta rays thereby to a large extent avoiding localized necrosis. Following the radon implantation, the abdominal wound is closed. The next day the patient may be put on a nourishing soft diet and in a short time allowed up and about. A few days following the healing of the abdominal wound, high voltage x-rays are directed to the stomach lesion, anteriorly and posteriorly through the abdominal wall. In this way additional radiation over a more extensive area is delivered to the tumor and surrounding tissues. In carcinoma of the stomach the pylorus is the most frequent site of the lesion. Of the three cases presented, two were pyloric tumors and the third involved nearly the entire stomach, presenting the so called leather bottle type. The result was good in two cases and bad in the third. The two patients were alive and comfortable, one after five months and one after two years. The third patient, with the leather bottle type stomach, died two months after treatment, having been bedridden continuously following treatment.

Simplified Method of Bronchography—Forestier and Leroux describe a modification of the method proposed by Hicquet and Hennebert, which consists in injecting the oil into the bronchial tree with a soft rubber catheter introduced into the nostril and farther down into the pharynx, larynx, and trachea. The authors found that the same route could be followed without the use of any catheter, the oil, and, previously to it, the anesthetic, being injected directly into one nostril with an ordinary glass syringe exclusive of any tip or catheter of any sort. The method is based on the following principles. When the tongue is pulled out of the mouth and grasped firmly the epiglottis is raised with the whole larynx, the upper orifice of the esophagus is closed and the patient is unable to swallow. If any fluid comes into the pharynx in this position, the only way open below is the glottis. The local anesthesia of the pharynx, larynx and trachea is made with exactly the same technic as the injection of iodized oil itself. The anesthetic solution is poured into the nostril and slides down to the glottis and later into the trachea, following exactly the same path which the oil will follow when bronchography is performed. No laryngeal mirror, swab or spray is necessary, and the technic may be performed by any qualified physician. The local anesthesia brought about by the

cocaine solution on the nasal and pharyngeal mucous membranes probably helps to stop the cough reflex arising in the laryngeal vestibule. Once the anesthesia of the larynx has been obtained, the tracheal bifurcation is anesthetized by injecting some more anesthetic into the bronchial tubes. The results of the method have been most satisfactory. Only one person out of several hundred is able to swallow the oil while the tongue is pulled out firmly. This procedure causes the patient as little discomfort as possible. Fluoroscopy can be performed while the injection of iodized oil is made. In the event of failure the use of a catheter passed through the nose may lead to success in a limited number of cases. In hospital work from four to five patients may easily be examined almost at the same time, the anesthesia being begun for each of them one minute after the other, and the whole set of cases can be examined within less than half an hour. The authors found the method without danger. A limited number of patients have experienced some dyspnea during the time of the injection. A subcutaneous injection of camphor oil with ether can control this symptom very easily. In case of active sinus or nasal infection the pernasal route should be avoided.

Neuropathology of Pellagra—Tucker attempts to correlate the alimentary and cutaneous lesions with the pathologic lesions found in the nervous system, discusses the latter and suggests a virus invasion as the possible etiologic factor in pellagra. The sequence of the symptoms of pellagra was first those of the alimentary canal, then of the cutaneous surfaces, nervous and mental manifestations usually coming later. In the alimentary canal the parts chiefly affected by pellagra are the mouth and the colon. The cutaneous lesions are bilateral and symmetrical and occur chiefly on the dorsum of the hands and the extensor surface of the arms, on the outer surface of the elbows, on the dorsum of the feet and the front of the knees, on the forehead ala nasae, cheeks and chin and less frequently on the front and back of the neck and on the labia or scrotum. Hence these lesions occur on either exposed or unexposed surfaces. Among the organic neurologic symptoms are tremors, muscular cramps, transient contraction of the limbs, mumbling speech, diminished hearing, diminished smell and diminished

taste, and the Romberg sign may be present. The most constant finding in six spinal cords and in two sympathetic spinal ganglions was gliosis. In the cords the posterior columns were especially involved. Other changes in both cords and ganglions were scattered chromatolysis, shrinkage of nerve cells, pigmentation, neurophagia and lysis or fragmentation of Nissl granules. Allowing for possible postmortem changes, it would seem that these alterations occur more markedly in pellagra than in most other diseases, although they cannot be considered specific for pellagra. All forms of degeneration were possibly more marked in the cervical and lumbar regions of the cords. The degenerations of the spinal sympathetic ganglions were extensive. The disease in its wide epidemiology, in its place occurrence, in its trophic lesions corresponding to root endings in its cord and spinal sympathetic ganglionic invasion in its apparent attenuation and in its recurrence reminds one of such filtrable virus diseases as influenza, encephalitis and infantile paralysis. The author believes that, if many more sections of the cord from the upper cervical region to the conus, of the sympathetic ganglions and of both motor and sensory peripheral nerves and sympathetic nerves are studied, pellagra will eventually be classified as a neurologic rather than a general medical disease and that it will be found that the distribution of the cutaneous and alimentary symptoms will be in relation to the lesions of the nervous system.

So-Called Ptomaine Poisoning—Goforth says there is no justification for the continued use of the expression ptomaine poisoning. Food infection, the invasion and growth in the body of pathogenic micro organisms capable of producing toxins, and food intoxication, a poisoning produced by toxins formed by bacteria in food before ingestion, constitute the largest and most important varieties of acute food poisoning. The organisms of the *Salmonella* group, particularly *Bacillus aertrycke* enteritidis and *supestifer*, are responsible for the majority of outbreaks of acute food poisoning. These organisms are capable of forming a heat-resistant irritant which can produce acute gastro-enteritis. The sources from which the organisms causing bacterial food poisoning are derived are not completely known. Protein foodstuffs particularly meat and milk products, are the vehicles of infection in the majority of instances. Laboratory methods are necessary in proving the diagnosis and etiologic factors of food poisoning. They should be more frequently employed when the physician makes his initial detailed study of the case. Accurate conclusions presuppose the support of pertinent clinical data. The increasing number of medicolegal cases of food poisoning emphasizes the necessity for the early, complete and accurate collection of data and materials for examination in each case by all associated with the case. The prevention of bacterial food poisoning depends to a large extent on the coordinated activities of the laboratory workers, the public health officer, the veterinarian, the nurse and the general practitioner. Rigid standards of sanitation regarding the preparation, preservation, handling and exposure of foodstuffs should be maintained. Extended research is needed to bridge the gaps in our knowledge of bacterial food poisoning.

Bronchomoniliasis—In two cases of nontuberculous disease of the lungs the Flinns isolated bronchomoniliasis and proved its pathogenicity by injection into the lungs of laboratory animals. In one case the diagnosis was confirmed by therapeutic test in the other the diagnosis was proved by postmortem study and recovery of the organism from necropsy specimens. Morphologically the infecting organism was a yeast-

like fungus belonging to the family Oosporaceae Saccardo. Biochemical studies enabled them to classify it definitely in the genus *Monilia* (or more accurately *Monilia Persoon*) and the species *Monilia Pinoyi*.

Presacral Ganglionectomy for Dysmenorrhea.—Duncan states that surgery of the pelvic sympathetic nerves for intractable dysmenorrhea has proved to be a safe and satisfactory method for the immediate and lasting relief of this periodically disabling condition. The operation can be performed by any competent abdominal surgeon and obviates the unsatisfactory temporizing methods of treatment in intractable dysmenorrhea or unnecessary hysterectomy or the use of radium or x rays, which are distinctly contraindicated in the young as a cure for this condition. The resection of the superior hypogastric plexus is safe and is not followed by any serious complications, and it in no way interferes with conception, gestation or delivery. The procedure is indicated in severe disabling pain at the menstrual period, which has existed over a period of time often associated with pain of a neuralgic type in the pelvis and back between periods. If no adequate explanation for this pain can be found on physical examination, and it has resisted all the usual methods of treatment, a good indication for a sympathetic resection exists if one wishes to give permanent relief. It is not indicated when at exploration, definite pathologic conditions are encountered that adequately account for the pain. Careful examination will show a high proportion of these cases showing a sclerotic change in the ovaries and these ovaries should not be removed as their function seems to become more normal after the sympathetic resection and anatomic improvement may also take place. Cysts of the ovaries should be resected the ovarian structure being disturbed as little as possible.

Hypertension Associated with Experimental Oxalate Nephritis—In their search for a nephrotoxic substance that might produce hypertension Arnott and Kellar used sodium oxalate. Fourteen chinchilla rabbits were used throughout the course of the experiments. Eight of these were placed on a relatively dry diet of oats and bran with an occasional cabbage leaf and no water. The other six received a cabbage diet with water as desired. One animal in each group served as a control. After a prolonged period of control lasting several weeks, the animals were given a course of sodium oxalate intravenously, the injection being repeated every second day. The initial dose was from 50 to 60 mg of sodium oxalate, which was raised after two injections to from 80 to 100 mg depending on the weight of the animal. The control animals received equivalent volumes of physiologic solution of sodium chloride intravenously, to eliminate the possibility that the mere bulk of fluid had any effect on the blood pressure. Blood urea nitrogen readings were made on all animals during the control period and on the animals that survived a period of three weeks of the oxalate injections. The average normal systolic pressure in the fourteen rabbits was 96 mm of mercury. It was found that repeated injection of sodium oxalate into rabbits results in a definite hypertension with a duration of approximately twelve days. Thereafter the pressure shows a pronounced instability although it never reaches such a height as during the initial period of hypertension. This hypertension appears sooner and is more pronounced in the case of animals fed on a dry diet. It is hardly surprising that there is to be found a difference in the reaction of animals on such diets as the conditions of renal function are so widely dissimilar. Those on a dry diet produce scanty concentrated urine rarely in excess of 50 cc daily, with occasional periods of anuria as long as thirty-six hours whereas those on the wet diet pass as much as 500 cc. of urine and rarely less than 150 cc. Whether or not this hypertension is of renal origin, the albuminuria, the nitrogen retention and the histologic picture indicate that at least it is associated with renal damage. The authors are unable at present to advance any evidence as to the mechanism by which the pressure is elevated although

they might suggest that it is in some way associated with glomerular ischemia resulting from the pressure exerted by the swollen tubular epithelium. The one common factor that is shared by most varieties of human renal disease associated with hypertension is some interference with glomerular circulation. It has to be realized, however, that, owing to the widely dissimilar etiology and histology, experimental oxalate nephritis sheds little light on human glomerular nephritis. They hope that this experimental production of hypertension may provide a basis for the investigation of the as yet unsolved relationship between renal damage and hypertension.

Influenza and the Preparation of Immune Serums in Horses—Laidlaw and his associates found that antinfluenza serum of significant potency can be made by hyperimmunizing horses with virus emulsions from ferrets suffering from acute attacks caused by human or porcine strains of influenza virus. Such hyperimmune serum will neutralize influenza virus in mixtures even after considerable dilution. This serum confers some degree of passive immunity to mice on injection. It has a beneficial action on mice already infected with the virus. Horse hyperimmune serum can be fractionated and concentrated. The greater part of the activity is found in the pseudoglobulin fraction of the serum and is precipitated in the fraction salted out between 12 and 16 per cent of sodium sulphate. The resolution of influenzal pneumonia in mice is a slow process and presents some peculiar features.

Influenza and Experiments on Immunization of Ferrets and Mice—Smith and his co-workers observed that ferrets after recovery from infection with influenza virus are completely resistant to reinfection for at least three months, thereafter the immunity slowly wanes. Ferrets with waning immunity still have significant amounts of virus-neutralizing antibodies, but in spite of the presence of these the nasal mucosa is susceptible to attack by virus. The waning immunity can be reinforced by subcutaneous inoculations of living virus so that once more the ferret becomes completely resistant. Subcutaneous inoculations of living or formolized virus produce in ferrets a partial immunity, characterized by the development of virus-neutralizing antibodies in the circulation and by an increased resistance of the lungs against virus attack. Similar immunization of mice with living virus has also a beneficial effect on the extent and course of the disease. The swine strain of virus (Shope, 1931) is immunologically related to but not identical with the two human strains studied.

Treatment of Obstetric Disproportion—Brown states that the recognition of gross disproportion can be made on the findings of gross contraction of the pelvis alone. It is therefore essential that every patient be subjected to a vaginal examination and that the diagonal conjugate be measured. The outcome of labor in cases in which minor disproportion is thought to be present is uncertain. A decision can be made only after labor is in progress. Pelvic measurements are not unimportant but must be considered in conjunction with all other factors before prognosis can be made. A vaginal examination should be made in every case during pregnancy. Induction of premature labor for disproportion has no place in the delivery of a primipara. Induction of premature labor is a useful method in the delivery of a multipara when a record of the history

of former labor has been carefully kept and can be used as a guide to the capacity of the patient to deliver herself. A trial of labor will estimate the patient's capacity for delivery, and no amount of skill can enable an observer to decide on this capacity during pregnancy. When induction of premature labor is practiced in the case of the primipara it may be done unnecessarily, and there is little to prevent the obstetrician from repeating this error in the treatment of future pregnancies.

Physiologic Effects of Reduced Cooling Powers—Lee and Mulder describe experiments in which human subjects in the postabsorptive state were kept at rest for six and one-half hours in hot rooms of two different humidities but of the fairly comparable "effective temperatures" of from 92 to 95 F. A standard meal and a standard amount of water were taken at stated times, and observations were made on pulse rate, body temperature, respiratory changes, urinary acid excretion, certain acid-base items in the cutaneous vein blood and symptoms. In subjects exposed to high temperatures, dry or humid the pulse rate and body temperature behave in a closely similar fashion. In the postabsorptive state they respond in equivalent fashion in environments of equivalent "effective temperatures," whether dry or humid, the taking of food, however, causes a greater reaction in the dry atmosphere. The value of Q_{10} for pulse rate in these experiments shows that the increase in rate is the result of complex factors. Respiratory changes are slight in the first three hours of the exposure they may become more marked subsequently. These changes are of the nature of increased depth rather than rate of respiration. Alveolar carbon dioxide tension does not fall until the respiratory volume has been markedly increased. Urinary acid excretion is lowered as compared with the normal room during the third to the sixth hour of the experiment. There is a definite fall in the carbon dioxide of cutaneous vein blood from the forearm. This appears before any fall in alveolar carbon dioxide tension. It is suggested that the causation is increased excretion of carbon dioxide through the skin, supplemented in some cases by an increased rate of cutaneous blood flow. Falling alveolar carbon dioxide tension may later cause a further lowering. The evidence for the existence of a true alkalemia of arterial blood, apart from overventilation, is inconclusive. There is no increased blood lactate content under these conditions. In the consideration of acid-base changes there is an urgent need for the reduction or so far as that is not possible, for the simultaneous study of variables simultaneous measurement of numerous items and rigid standardization of conditions.

Large Doses of Potassium Chloride in Myasthenia Gravis—Laurent and Walther determined the level of potassium in the blood plasma of ten normal subjects and of six patients presenting myasthenia. They used the following method of potassium estimation. Clear, nonhemolized serum or plasma is deprived of protein by means of tungstic acid and the clear supernatant fluid is treated with nearly saturated sodium cobaltic nitrite solution to precipitate the potassium as potassium sodium cobaltic nitrite. The precipitate is washed with distilled water and a solution of metaphenylenediamine hydrochloride is added and the precipitate allowed to dissolve in this acid solution in the boiling water bath. A yellow color is produced, varying in intensity with the concentration of nitrite. This color is compared with the color produced by a standard potassium solution similarly treated in a colorimeter. The advantages of the method are speed, simplicity and sensitivity. An adequate color is produced by quantities as low as 0.2 cc. of plasma, provided a microcolorimeter is used. The ten normal subjects had respectively 21.4, 17.5, 22.5, 15.2, 15.9, 15.8, 15.8, 17.0 and 18.0 expressed in milligrams per hundred cubic centimeters, while the six myasthenic patients had 15.7, 16.4 later 13.8, 15.2 later 15.8, 14.2, 15.8 and 15.2. Three patients with myasthenia were given 2 Gm of potassium chloride orally five times a day, each dose being dissolved in half a glass of water. They all reported some subjective improvement, starting half an hour after each dose and passing off in the course of the next hour. The authors observed slight diminution in ptosis, slight improvement in the range of ocular movement and increases of from 3 to 5 pounds in the power of the grasp. Large single doses were administered to five patients in the hope of obtaining a more clear cut improvement. Ptosis, external ocular movements and facial appearance were improved to a greater extent than the limbs, although the recording dynamometer showed constant increase in the power of the grasp of from 3 to 15 pounds according to the case. In two cases the plasma potassium was determined before and an hour after the ingestion of 12 Gm of potassium chloride. A considerable rise took place in each case. The preliminary figures were 14.7 and 15.2 mg per hundred cubic centimeters, and they increased to 22.6 and 27.4 respectively. Six patients with myasthenia took from 4 to 6 Gm of the salt six times daily. This treatment was a valuable adjunct to prostigmine (a derivative of physostigmine). Several of the patients found that a dose of potassium chloride taken before the action of prostigmine has ended relieves the feeling of exhaustion and to some extent prolongs the improvement brought about by this drug. The results obtained with the largest doses of potassium chloride tolerated by the patients are still somewhat short of the effect of 0.5 mg of prostigmine given by injection. The authors conclude that potassium chloride, when administered orally in doses of from 10 to 12 Gm., gives a demonstrable improvement in myasthenia and that in small repeated doses it is a useful adjuvant to prostigmine.

Importance of Mucin in Equilibrium of Gastric Acidity—R. H. Vonceaux —p. 988

Parathyroidectomy and Chronic Rheumatism—Berard and his co-workers discuss the question of parathyroidectomy for chronic rheumatism. The clinical indications are uncertain, and failures occur apparently regardless of the type of the rheumatism. They believe that parathyroid extract produces in certain cases modifications of the oscillometric curve. This action of the extract verifies the reality of the close relation between the parathyroid and vegetative systems. The suddenness of the improvement in certain cases and the rapidity of relapses confirms the impression of nervous action. The most effective operation is the ablation of a portion of the parathyroid system, even though this is not the cause of the pathologic syndrome. It is a symptomatologic treatment acting through the intermediary of the vegetative system. The obscure point is the nature of this connection. The simplest hypothesis is that parathyroid extract regulates the relation between sodium \times potassium and calcium \times magnesium. If this is verified, the improvement of a chronic rheumatism would be the conclusion of a series of phenomena which, starting with a disturbance of ionic equilibrium of the blood by the parathyroid, ends in a modification of vegetative excitability.

Gastro-Esophageal Sensation of Burning—The group of patients treated by Gaston-Durand comprised those having gastroduodenal burning sensations with migraine, with urticaria with a combination of the two, and with migraine and angioneurotic edema. Twenty-one patients (fifteen women and six men) were observed. A first series of daily subcutaneous injections of parathyroid extract was given. Five units was employed on the first day to test the susceptibility of the patient and 10 units on the succeeding days. From 15 to 20 units was given in some cases of severe disorder. Twelve injections were given in the series. In the three or four following weeks, bismuth subnitrate, kaolin, magnesium or acacia was administered orally a half hour before meals. A month after the first parathyroid series, a second series is given with subsequent alternation of these procedures. In one case there was complete failure (after two series), in four there was partial failure, in four there was marked improvement and in twelve there was such a notable improvement that the patients could be considered cured. The author states that this method of treatment cannot be applied to all cases and is not infallible but offers more hope in selected cases than any other method that he has tried.

Revue Française de Pédiatrie, Paris

11: 265-408 (No. 3) 1935

- Studies on Infantile Acrodynia Annual and Seasonal Frequency E. Leenhardt and J. Boucomont —p. 265

Sugar of Blood and Cerebrospinal Fluid A. V. Tcherkassov and E. E. Jolkver —p. 350
Anemia of Mother and Child S. Van Creveld and N. I. Heybroek —p. 365

Origin of Infantile Allergy—Woringer studied sixty-six allergic infants from the standpoint of allergic family history and particularly of other cases of allergy in the direct ancestors. For twenty-two (33½ per cent) the inquiry was negative. Forty-four infants had one or more cases of early eczema among their direct ancestors or in the preceding collateral generations. Twenty-three times (35 per cent) the family of the mother was affected seventeen times (26 per cent) that

of the father and four times both sides. The allergies of the same family were always identical from an etiologic standpoint. The children of the same parents were affected with allergic disorders in a variable proportion, but usually the unaffected members predominated. The author believes that these facts cannot be explained either on the hypothesis of a postnatal sensitization or by an intra-uterine sensitization. They favor the hereditary origin of infantile allergy. This type appears as a character transmitted by gametes according to mendelian laws and seems to be recessive.

Blood and Cerebrospinal Fluid Sugar—Tcherkassov and Jolkver studied seventy-four patients with different forms of meningitis. They made 149 parallel determinations of the blood sugar and of the cerebrospinal sugar in these patients. They conclude that the quantity of fasting blood sugar in mild cerebrospinal meningitis does not show any pronounced deviations from normal. In the severe forms an increase paralleling the severity of the process is present. In tuberculous meningitis it is more often above normal. The quantity of sugar in the cerebrospinal fluid during meningitis varies according to the etiology. In tuberculous meningitis it is markedly diminished and falls progressively with the development of the disease. In cerebrospinal meningitis it varies with the course of the disease. At the beginning it is always below normal and later the quantity increases as the process improves, in serous meningitis the quantity of the spinal fluid sugar diminishes a little at the onset, but less pronouncedly than in cerebrospinal or tuberculous processes. The proportion of blood sugar and cerebrospinal sugar in the course of tuberculous and cerebrospinal meningitis shows a higher value than normal, owing to the diminution of sugar in the fluid. In serous meningitis the proportion is reversed, owing to the increase of sugar in the cerebrospinal fluid. The glycemic curve in the toxic forms of cerebrospinal meningitis and in advanced cases of tuberculous meningitis does not return to the initial level even after two hours and sometimes does not reach its maximum until this period. The attempt to push sugar on the patients with meningitis aims at the definition of the functional state of the blood brain barrier but is in no way preferable to other methods employed for this object.

- Extrapyramidal Nervous Syndrome of Malarial Origin Case V. Chini —p. 389
*Spontaneous and Provoked Ketonemia as Functional Test of Liver P. Zorzoli —p. 405
*Resistance of Leukocytes in Acute Diseases of Respiratory Tract of Children. V. Serra and S. Colbi —p. 425
Creautemia in Muscular Hypertonia of Extrapyramidal and Pyramidal Origin G. Cardinale and G. Arnone —p. 441

Ketonemia as Functional Test of Liver—Zorzoli studied the behavior of ketonemia after the intramuscular injection of epinephrine alone and in combination with sodium butyrate by the oral route in normal persons and in three groups of patients suffering from liver diseases, diabetes and hyperthyroidism, respectively. For the estimation of the results of the tests the patients suffering from liver diseases are placed in two groups according to the value of spontaneous ketonemia during fasting, which is higher than normal in those having the febrile and acute type of the disease and jaundice, and lower than normal in those suffering from the chronic type especially in patients who are in the advanced stages of atrophic cirrhosis. As a result of the tests, ketonemia increases both in normal persons and in patients of the first group having liver diseases, but the increase of ketonemia in the latter is higher than that in the former. The curves of ketonemia in patients of this group are similar to those given after the same tests by patients suffering from either diabetes or hyperthyroidism. Ketonemia in patients of the second group fails to react to the tests or reacts poorly. The more advanced the disease is in this group, especially in those suffering from atrophic cirrhosis, the greater the insufficiency of the liver and the more marked the lack of response of ketonemia to the tests.

Resistance of Leukocytes in Respiratory Diseases in Children—Serra and Colbi state that the fragility of the leukocytes increases during the evolution of acute diseases of the respiratory tract of children. The intensity of the fragility

does not have any relation to the age of the patient or to the duration of the disease. The leukocytes start regaining their resistance one or two days after the febrile crisis if there are no recurrences or complications. While the fragility of the leukocytes has no prognostic value, its persistence after the crisis has. A decreased resistance of the leukocytes in one case represents a defensive reaction of the organism against the infection similar to the appearance of fever and leukocytosis in some infections, while in another it indicates the presence of new pathologic foci or the development of some other infectious disease as a complication and coexists with the persistence or reappearance of fever. The fragility of the leukocytes appears to be the result of an injurious action of the bacteria and their toxins, both directly on the leukocytes in the blood and indirectly by a pathologic stimulation of the bone marrow. The predominance of lymphocytes over leukocytes during the reversion of the leukocytic formula that follows the febrile crisis is probably the factor by which the resistance of the leukocytes increases after the crisis.

*Speed of Sedimentation of Erythrocytes in Pick's Disease H. Basabe—p. 1890

Sedimentation Rate in Pick's Disease—Basabe states that retarded sedimentation speed of the erythrocytes in patients with the clinical picture of Pick's (Friedel) disease is of value in the diagnosis. The fact that the velocity is increased in tuberculosis and in rheumatism indicates that the etiology of Pick's disease is neither tuberculous nor rheumatic. The abdominal symptoms in patients suffering from Pick's disease, especially the obstinately recurring ascites, mask the clinical picture and suggest a mistaken diagnosis of tuberculous peritonitis. The systematic performance of the Rivalta reaction of the ascitic fluid for determination of its nature, either exudative or transudative, as well as of the other laboratory tests commonly used for detection of tubercle bacilli, is advisable in all cases of tuberculous peritonitis for the differential diagnosis between this condition and Pick's disease. In the latter the retarded sedimentation speed coincides with negative results of the Rivalta reaction and of the other tests for tubercle bacilli and with a lesion of the pericardium, detectable in careful examination of the heart. On the other hand, acceleration of the sedimentation of the erythrocytes and positive results of the Rivalta reaction or of the other reactions for tubercle bacilli in a diagnosis of Pick's disease indicate that the diagnosis should be verified. A case of Pick's disease is reported.

Enlargement of Pelvis by Means of Hormones—Tapfer and Haslhofer call attention to the fact that a considerable expansion of the pubic symphysis and of the sacro-iliac joints takes place during pregnancy and delivery. They review the literature on the causes of this pelvic enlargement, citing animal experiments carried out by several investigators. They show that nearly all workers agree that the pelvic enlargement in pregnant guinea pigs is due to the action of certain hormones. However, there is no agreement as to what hormone produces this pelvic enlargement, whether the estrogenic or the corpus luteum hormone, and to determine this the authors made experi-

ments on guinea-pigs. They used the serum of pregnant rabbits to obtain enlargement of the pelvis without artificial hormone and organ preparations. It was found that this serum produces in nonpregnant guinea-pigs an expansion of the pubic symphysis like that taking place during pregnancy and was the more effective for enlargement of the pelvis, the closer the pregnancy was to its termination. The authors demonstrate that the behavior of the pubic symphysis of guinea pigs toward the serum of pregnant rabbits indicates clearly that the enlargement of the symphysis and the action of the corpus luteum do not run parallel. Experiments on castrated animals indicated that the estrogenic hormone is the active substance in the pregnancy serum. Subsequently the author tested also artificial hormone preparations and found that estrogenic substance alone is capable of producing an enlargement of the pubic symphysis. Microscopic studies disclosed that the expansion of the pubic symphysis produced artificially by estrogenic substance is identical with that of pregnancy.

Determination of Urinary Pigments—In colorimetric studies on specimens of the urine of 465 women from gynecologic and obstetric departments Winter employed absolute colorimetry by means of gray solution and spectral filters. He reviews observations made by others by means of the step photometer. The elimination of urinary pigment has been known to be increased following irradiations with roentgen or radium rays. This increase has been ascribed to an impairment of the liver or to a greater decomposition of erythrocytes, the latter possibility being considered most likely. Another investigator detected increased pigment content of the urine during pregnancy and ascribed it to a greater blood exchange during pregnancy. The author observed that in some cases of carcinoma, nephropathy and eclampsia the color values were on the upper limits of normality or slightly above these limits. He never observed great deviations from the normal and consequently does not draw conclusions regarding the function or abnormal function of an organ (perhaps the liver) or of a system, such as the erythropoietic or the reticulo-endothelial system. The colorimetric studies on the urine are of theoretical interest and doubtless are an aid to further research but have as yet no practical clinical value for the gynecologist.

Pathogenesis of Galactorrhea—Kraus says that the majority of cases of galactorrhea occur in women (rarely in men) with disturbances in the hypophyseodiencephalic system, particularly in patients with acromegaly. He describes two cases of galactorrhea in nulliparas in whom there existed a partial hyperpituitarism caused by hyperplasia of the anterior lobe of the hypophysis with an increase in the eosinophil cells and with proliferation of hypertrophic main cells, some of them resembling pregnancy cells. The ovaries showed signs of degeneration. The author sees the cause of the galactorrhea in these hypophyseal and ovarian changes. The fact that the continued stimulus of suckling is capable of producing lactation even in virgin animals and that lactation may develop during false pregnancy indicates that the secretory organs particularly the hypophysis are stimulated by way of nervous channels. Under pathologic conditions lactation may develop under the influence of a partial, lactogenic hyperpituitarism in which deficient or abolished gonadal function is a contributing factor.

*Further Studies on Formerly Unknown Decomposition Product of Blood Pigment (Pentdyopent) in Urine F. Wimplinger—p. 1072

Dysentery During Childhood—Loeschke shows that in severe toxic dysentery two conditions predominate, the loss of water and of body fluids and the flooding of the organism with toxins. He says that although the efficacy of therapeutic serum is doubtful, it should be injected. If considerable dehydration has taken place or if it threatens and with it the danger of secondary intoxication, infusion should be resorted to, preferably in the form of the continuous drip. If the toxic symp-

toms persist for longer periods, the transfusion of small quantities of blood (from 100 to 200 cc) is advisable. If there are signs of increasing cerebral edema, concentrated dextrose solutions should be tried intravenously.

The Pentdyopent Test—Wimplinger calls attention to a decomposition product of the blood pigment recently discovered by Bingold and called pentdyopent, a name that designates the spectroscopic localization of the substance. In the Schunim-Loewe grating spectroscope it is indicated by a sharply defined line that has its maximum at 525 (pentdyopent) micromicrons. The substance is free from iron and protein and readily soluble in water. In alkaline solution (in case of the addition of potassium hydroxide or ammonia and of reduction with the aid of sodium thiosulphate) the substance has a pleasing red color. Spectroscopic analysis is possible only following these preparatory measures, for the nonreduced substance in the nonalkaline reaction does not permit this. If present in the urine, the substance is readily detectable. To 10 cc of urine, approximately 2 cc of solution of potassium hydroxide is added and the mixture is boiled. Following filtration, this urine is reduced by means of small quantities of sodium thiosulphate and is boiled again. Spectroscopic examination discloses at about 535 micromicrons a sharply defined line, which has its maximum at 525 micromicrons. Urobilinogen and urobilin can likewise be detected in the spectroscope. The author searched for pentdyopent in 1200 specimens of urine. He found that it is always detectable when conditions exist that cause the elimination of bile pigments. The first group of specimens in which pentdyopent was found came from patients with icterus. In certain infectious diseases such as pneumonia, Weil's disease, typhoid and various types of sepsis, pentdyopent was present, as was the case also in a number of cardiac disturbances in which conditions of stasis existed. Pentdyopent was found in cases of hepatic disturbances, but not to the extent to which it had been expected. It had been assumed that in certain diseases of the blood particularly pernicious anemia, pentdyopent would appear in the urine in large quantities, but this was not the case in fact, the substance was entirely absent. The same applies also to cases of lymphogranulomatosis and leukemia. Uncomplicated renal diseases and acute and chronic gastro intestinal disturbances gave negative results. The author points out that numerous tests on the blood serum of patients who eliminated large quantities of pentdyopent in the urine were nearly all negative. Bingold himself has found traces of the substance in the erythrocytes and has demonstrated by test tube experiments on hemoglobin that the substance is actually a derivative of the blood pigment. The pentdyopent test has diagnostic significance, the negative outcome even more than the positive one. For instance, if the question arises as to whether a hepatic disorder is present or another organ is involved, the absence of pentdyopent from the urine permits the exclusion of a hepatic disorder.

- Significance of Number of Cells in Inoculation of Adenocarcinoma of Mouse G Witte—p 251

Spondylolisthesis—Meyer-Burgdorff and Sandmann in discussing the pathogenesis of spondylolisthesis point out that as yet there is no definite proof of the congenital nature of the disorder. They show that, whereas some investigators stress the importance of 'congenital spondylolysis' that is the cleft in the lateral portion of the vertebral arch others, particularly Blume, stress the destruction of the intervertebral disk between the fifth lumbar and the first sacral vertebra as the most important factor. The authors criticize the specimen on which Blume made his studies and on the basis of which he stressed the degeneration of the intervertebral disk as the

important factor in the development of spondylolisthesis. They show that in this specimen there existed severe malformations in the form of a congenital kyphosis with misplacement of the bones, fusions, arch defects and so on. They maintain that Blume's specimen does not represent a spondylolisthetic disorder. They state that the question investigated by Blume, whether the primary cause of the slipping is to be found in the intervertebral disk, has been the subject of their investigations for two years. On the basis of clinical and roentgenologic observations and of animal experiments they conclude that a degeneration of the presacral intervertebral disk occurs quite frequently in older persons without subsequent slipping, but that lateral vertebral clefts develop with the same frequency without the least indication of a degeneration of the intervertebral disk. The authors tested the resistance of the presacral intervertebral disk on dogs. Among nine dogs there was one in which "sliding" of the lumbar vertebra on the sacrum could be produced after seven months of observation. By taking out lateral and posterior portions of the arch, it was possible to make the intervertebral disk between the last lumbar and the first sacral vertebra yield and produce a slipping of the vertebrae. The result of this experiment largely resembles spondylolisthesis in human subjects. The authors conclude from this that the degeneration of the intervertebral disk cannot be the cause of spondylolisthesis but that the presence of a lateral cleft in the arch, that is, spondylolysis, is the cause. However, they were not able to prove the congenital nature of spondylolysis.

Localization of Surgical Disturbances in Central Nervous System—Nagai reports that, in thirty patients with spinal disorders and signs of pressure myelitis, he was able to determine by means of chronaxia measurements changes caused by the disease focus. In all the patients he observed in the region corresponding to the focus either a prolongation or a shortening of the chronaxia. He generally observed a shortening in the new cases and a prolongation in the old cases. The chronaxia likewise disclosed fluctuations in the muscles belonging to the segments below the segment involved by the focus, but they were of a milder degree than the ones in the region of the focus. The author concluded that the change in the chronaxia in the region corresponding to the focus is helpful in localizing the focus. He made use of the chronaxia test also in twenty cerebral processes. He points out that the motor centers are localized chiefly in the gyrus centralis anterior. He thinks that a change in any of the centers would be followed by a change in the chronaxia of the subordinated nerves and muscles. He actually found considerable conformity between the results of the chronaxia tests and observations during the surgical intervention. He reaches the conclusion that the chronaxia test is superior to the formerly employed physical methods, because it avoids unpleasant after-effects and is simpler.

- *Pectins as Substances Accelerating Blood Coagulation O Riesser—p 958
- *New Method of Rapid Histologic Diagnosis in Its Significance for Surgery of Brain M de Croux—p 961
- Temperature Regulation H H Meyer—p 962
- Group Formation of Diphtheria Bacilli J Hammerschmidt—p 964

Cushing's Syndrome—Hildebrand points out that Cushing has separated from the group of so-called polyglandular disturbances a definite syndrome and has shown that a basophil adenoma of the hypophysis is the cause of this condition. While acromegaly is the result of a hyperfunctioning of the eosinophil cells this new syndrome is the result of a hyperfunctioning of the basophil epithelia. Pituitary basophilism has been described by others under such terms as multiglandular disease, osteoporotic obesity, hypophyseal plethora and diabetes of bearded women. Because it cannot be decided as yet to what extent other glands are involved in addition to the hypophysis the author thinks that each new case of Cushing's syndrome should

be carefully studied. He gives the history of a man, aged 53, who had an abnormal carbohydrate metabolism with signs of insular diabetes, an obesity that was localized on the head, neck and trunk and in which there was a tendency to hypercholesteremia, no demonstrable disturbance in the protein metabolism, a severe decalcification of the bones with hyperphosphatemia, slight hypercalcemia, negative calcium balance and a slightly positive phosphorus balance, follicle maturation principle in the urine, but no gonadotropic principle in the cerebrospinal fluid, reduced basal metabolic rate with unusually strong specific dynamic action, intact renal function, and increase in the systolic and diastolic blood pressures but no increase in the quantity of blood. On some portions of the patient's body the skin was extremely thin, so that the subpapillary venous plexus was quite noticeable, and to this was ascribed the sensitivity for mechanical injuries. There was sexual dystrophy. The patient's previous history disclosed a temporary polyuria and polydipsia. The author thinks that these symptoms make the existence of a basophil adenoma highly probable.

Pectins Accelerate Blood Coagulation—Favorable clinical reports on the hemostyptic action of pectin induced Riesser to investigate the action of pectin on the coagulation of blood. He experimented on rabbits, using a sterile, isotonic apple pectin. The preparation was administered to the animals intramuscularly, orally or intravenously. All these methods of application resulted in a considerable acceleration of the coagulation time, occasionally reaching such a degree that it was impossible to get noncoagulated blood into the tube. The animals showed no other manifestations. In discussing the mode of action of pectin, the author points out that in vitro pectin has a tendency to retard rather than promote coagulation. From this he concludes that the action of pectin is an indirect one and that the active substance is formed as the pectin comes into contact with the endothelium of the vessels.

Rapid Histologic Diagnosis in Surgery of Brain—To find a rapid method for histologic examination, de Crinis used a micropolychromatic device that permits the optic coloration of microscopic objects. The micropolychromatic instrument is a shutter mechanism attached to the illuminating apparatus of the microscope and permits the simultaneous use of the light and dark fields with and without optic coloration. The author describes its structure showing that it is a dioptric dark field condenser. The examination of the tissue is done in the following manner. A quantity of the tissue or the punctate equal to half the size of a pinhead is put on a slide and prepared by means of teasing needles in physiologic solution of sodium chloride or a 1 or 2 per cent bichromate solution. A cover glass is pressed over it and it is examined under the microscope with the polychromatic attachment. It is unnecessary to prepare a completely teased specimen, because the diagnosis is easier if cells can be observed both inside and outside the tissues. Not all color combinations are of equal value for the examination. He found the contrast violet and green most suitable, the first for the colored dark-field illumination and the second for the background. He shows that the method is suitable also for the demonstration of cells in the cerebrospinal fluid. He concludes that the histologic examination of the tissues with the aid of the micropolychromatic device, because of its simplicity and rapidity, is a valuable aid in cerebral surgery.

 *Spontaneous Thrombosis of Inferior Hemorrhoidal Plexus K. Blood.—p 880
 Severe Anemia Induced by Self Injury G. Parper—p 883
 Physical Diagnosis of Lungs F. Besdzick—p 884

Thrombosis of Inferior Hemorrhoidal Plexus—Blond states that thrombosis in the region of the inferior hemorrhoidal plexus is the most frequent spontaneous thrombosis in the human organism. These nodules are extremely painful. If they are incised within the first eight days after their development, a dark red discharge can be pressed out. If more than eight days has elapsed, the nodule can be excised only by removing the venous wall. Not until the proctoscope with the lateral

window was available could these cases be subjected to an exact examination. The author injects an anesthetic under the nodule, opens it by means of a puncture incision and evacuates the thrombus by means of lateral pressure. The subsequent proctoscopy, which is usually painless, reveals varices in the region of the superior hemorrhoidal plexus which should be obliterated at once. Their obliteration, however, differs from that of varices of the lower extremities. He makes submucous injections without aiming at or achieving thrombosis. In answer to the question why spontaneous thromboses develop in this region, he points out that this is the "divide" between the portal system and the vena cava and that the reflux of portal blood into the vena cava is one of the chief factors in spontaneous thrombosis. Since the presence of varices within the rectum is a grave danger during pelvic operation, he advises that every surgical intervention within the pelvis be preceded by an examination of the extremities and by proctoscopy to determine the condition of the rectal veins. Varicose conditions in these regions signify danger of embolism and should be properly treated first.

Münchener medizinische Wochenschrift, Munich

Abdominal Myalgia—According to Klingler, abdominal myalgia is a form of muscular rheumatism. It is comparatively rare but of great differential diagnostic significance. The author observed cases of abdominal myalgia erroneously diagnosed as colitis, enteritis, colic, gastralgia, gastric ulcer, renal, ureteral or biliary calculi, cardiospasm, angina pectoris and so on. He reports several cases. Myalgia may resemble neuralgia, but careful observation will reveal its myalgic character, for the pain follows the muscle and not the nerve. If the myalgia is localized in the lower part of the abdomen, intestinal colics and dejection are the predominating symptoms, but, if the upper part of the abdomen is involved, vomiting and cardiospasm are often observed. Pectoral myalgia is accompanied by cardiac symptoms. To counteract the disorders, it is necessary to treat the primary myalgia. The author did this successfully by the application of heat and massage and by the injection of a 10 per cent solution of dextrose.

Source of Error in Staining for Schüffner's Stippling—Giemsa points out that, if slides of blood from tertian malaria are stained with Romanowsky's method, the erythrocytes that have been attacked by the parasites show a peculiar red stippling which increases with the age of the plasmodia and to which Schüffner, their discoverer, ascribed great diagnostic value in the recognition of this type of malaria. Romanowsky's method was not quite perfect until it had been recognized that the staining of these granules was possible only when the stain had a weakly alkaline reaction. Giemsa had obtained perfect results for years, but suddenly he noticed failures. Since the same kind of dye was being used, the cause could not lie in the dye solution. He soon discovered the cause in the fixing agent for, whereas formerly he had always used the purest methyl alcohol, he had been using a cheaper, somewhat less pure, type of alcohol when the mistakes were first noticed. Comparative tests with the two types of methyl alcohol soon disclosed that the degree of purity of the methyl alcohol is of great importance for the demonstration of Schüffner's stippling. What types or impurities caused the mistakes could not be determined as yet. The author recommends the use of buffered water. He dilutes his stain solution with a buffer solution with a pH of 7.2. He states that other types of granules, such as the Ziemann stippling in quartan malaria and Maurer's spots in tropical malaria, as a rule become visible only in case of a slightly higher pH (7.5). Whether impure methyl alcohol impairs the staining of these types of granules also, the author had no opportunity to observe.

CLINICAL INVESTIGATION PHYSICIAN AND PATIENT

THE NINTH ALPHA OMEGA ALPHA
ANNUAL LECTURE

GEORGE R. MINOT, M.D.
BOSTON

I plan to consider only certain aspects of clinical investigation especially referable to the physician and patient—thoughts about which have been fermenting in my mind for several years—rather than to present an exposition on all phases of the subject.

The medical student is trained by university education to use his own mind and to do his own thinking. Moreover, so long as he is active in medicine he must continue his education and constantly sharpen his powers of observation and judgment. At the bedside this attitude is essential. Doctors deal with human problems. To solve human problems, an active creative imagination and scientific curiosity are necessary tools. Such qualities are needed by the physician not because every doctor is expected to conduct investigations leading to new knowledge but rather because every patient who consults a doctor presents a problem for investigation before the best advice can be offered. Thus basically each practitioner of medicine is a clinical investigator, though research is not the *sine qua non* in making a clinician. The physician becomes inefficient and nonprogressive unless he is inspired by imagination and the curiosity to learn. It is important, therefore, that he should appreciate the spirit and understand the principles of research, and also develop an investigative habit of mind. These attributes must be applied at the bedside in the elucidation of the phenomena of disease. There is another goal that must be kept in mind. Since medicine deals so essentially in human problems, the physician must constantly strive to broaden his outlook on life, and he may do this by cultivating interests that may appear extracurricular to the practice of medicine.

WHERE UNDERTAKEN

Clinical investigation may be pursued in institutions designed only for that purpose or in any hospital. It may also be undertaken in offices for private practice. The establishment of laboratories and opportunities for clinical investigation in large hospitals where the study of patients under controlled conditions can be undertaken seems especially wise. On the one hand it surrounds the investigators with a wealth of clinical

material for study which offers opportunity for the origination of ideas and, on the other hand, it plays an important role in maintaining the hospital as a modern institution and permits patients to receive the very best treatment. There is nowhere that a patient stands so good a chance of being benefited as in a clinic where his disease is arousing scientific curiosity. The large general hospital that does not deliberately, wholeheartedly and intensively further the development of research or keep up with progress soon becomes one that goes backward.

To many persons the word laboratory implies a place where test tubes and complicated apparatus are employed to satisfy intellectual curiosity. The clinical investigative laboratory is not of that order, for wards with patients are the salient feature. The sick individual is the center of the picture. It is from the patients' problems that clinical investigations originate and these are not confined within the walls of a building. Indeed, clinical investigation goes far beyond the hospital grounds or doctor's office, because solutions to a given problem may be found at a distance, for example, in the social or economic aspects of the country, the community or the home. Although technical apparatus may be required for the proper care of the patient and for intelligent observation to promote the welfare of mankind, it is the least significant feature of clinical investigation. The most valued and most impressive possession of a clinical investigative unit, besides the sick people, is the accumulated records containing consecutive data often largely obtained by simple procedures and frequently entirely by the use of the intellect. One of the important methods of science is to create detailed trustworthy records of natural phenomena. It is from such information that concepts regarding the nature, treatment and prevention of disease are formulated and lead to the establishment of useful new knowledge. The foundation of such work lies in the quality of the minds of the staff and the freedom and tranquillity permitted for the use of their abilities. Free choice of problems and free choice to follow leads disclosed must be the privilege of the investigator.

THE MAN

The term clinical investigator is usually thought of as being applied to a man who devotes a considerable amount of time to the study of clinical problems in organized clinical laboratories. A man may devote his life to problems pertaining to the clinic but essentially never observe a patient. Such an individual, invaluable to the progress of medicine, may work, for example, in a laboratory of experimental medicine or in a chemical or physiologic laboratory, but for purposes of discussion here I do not refer to such an individual as a clinical investigator.

The William W. Root Lecture of Alpha Omega Alpha Honor Medical Society read at the annual meeting in Atlantic City, N. J., June 13, 1935. From the Thorndike Memorial Laboratory, Second and Fourth Medical Services (Harvard), Boston City Hospital and the Department of Medicine, Harvard Medical School.

A trained clinical investigator may mean a different type of individual to different people. Broadly speaking, it seems to me that there are two types of clinical investigators and that the distinction between them has not been well understood. The first is the experienced clinician who seeks tools through which to solve problems that originate in his mind at the bedside, for example, the man who observes in several patients an abnormal color of the skin and decides that, as an aid to determine its cause, chemical procedures must be utilized. The second also may have clinical training, but he is the trained technician who takes his tools to the bedside to apply them to problems he may be interested in, for example, a man trained in chemistry who seeks a patient that he believes will elucidate the mechanism of pigment formation. The former is more truly the clinical investigator, and it is by the intellectual rather than by the technical method that he approaches his problems. In any event the investigator must fertilize his plots with carefully tested mixtures of thought and knowledge gleaned from experience, books and journals, suggestions from colleagues and eternal painstaking study. He should have as his ideal the ambition to be the best possible man in his chosen field and among other qualifications, he must be industrious, alert, and able to progress by use of constructive imagination.

Both types of clinical investigator have their place in the development of useful knowledge and can profitably be found in the same hospital unit. However, if aggregations of individuals chosen only because they are acquainted with special techniques form the personnel of a clinical investigative unit, the practical needs of clinical medicine are apt to be forgotten. Likewise, the type of man more interested, for example, in chemistry than in the patient will not be as valuable to the hospital's total interests, including the patients and students therein, as the type of man who is chosen because of his clinical ability, scientific curiosity and an aptitude to formulate clinical problems and to foresee a way to solve them.

There is a strange fascination about research, which in the past quarter century has tended to make it a fashionable undertaking for the young physician. Remember, however, that a doctor should choose the field that will bring him happiness and should never pursue a career in the spirit of "it's the thing they all do." Much time has been wasted by men attempting things for which they have neither qualification nor training. Practitioners have suffered by believing they were research workers and good investigators have been lost to the world by their trying to become general practitioners. A man with an active medical practice, however, can contribute importantly to medicine although often lack of time and the character of his interests prevents or interrupts investigative studies. It is, indeed, the practitioner with limited practice—hospital or otherwise—who often becomes the most successful trained clinical investigator. The problem lies in the man himself rather than in his precise occupation, he needs to have a desire for adventure, a collecting or acquisitive spirit and a craving to learn about the unknown. He who undertakes clinical investigation, however, must learn to recognize clinical facts and never jeopardize the patients' health. He must establish a detailed diagnosis as rapidly as possible and not let science encourage him to waste time over unessential details but proceed to action for every aspect of the patient and his case. Training in investigative

ways most assuredly leads to better clinical work although some men who have spent much time in research laboratories or wards become poor practitioners. This is not the fault of the laboratory but the fault of the man himself. He must see to it that he receives proper training as a clinician.

Besides what is gained by investigative work itself, this type of work has a large educational value. Throughout life the physician must keep abreast of the times, and he should be surrounded by associates from whom he can constantly imbibe knowledge. An understanding of the principles of investigative work can lead him to judge critically, to appreciate the nature and significance of proper controls and to distinguish the chaff from the wheat of medical papers. Every physician must be trained to look at problems from numerous angles and be unwilling to confine himself to standardized procedures, no matter how successful they may be in contemporary industrial life. Mass production cannot be used in medical service. As each bit of information is added to the sum of human knowledge it is evident that it is the little things that count that give all the fertility and character, all the hope and happiness, to human affairs.

THE STUDIES

Clinical investigation takes a variety of forms, and much work properly belonging under that title would not be called research in the strictest sense of that term. The aim should be, however, to undertake fundamental problems and to appreciate that progress in the clinic may owe its origin to the fields of pure science. Sir Thomas Lewis has written on the scope and methods of clinical science and considers that work in this field consists of studying diseases as diseases or as some manifestation of disease that several diseases have in common. Therapeutics is essentially an experimental science and will always have experimentation on man for its chief basis. It is linked with pharmacology, and a clinical investigator may find that he is, at least for his own purposes, the best pharmacologist. Many clinical investigative studies are of a simple routine collective nature such as the analysis of clinical data, the evaluation of new procedures or the correlation of clinical and chemical or pathologic studies. A complete study of a case and the literature concerning it, with some special observations followed by a carefully written report as Herrick has said, will do much to clarify the doctor's own knowledge and may help clarify knowledge for some one else. Such work sharpens powers of observation and tends to prevent conclusions based on mere impressions and leads to obtaining facts. Descriptions of heretofore unrecognized conditions often depend on the good fortune of observing several cases and not on planned investigation. Collecting proper information over long periods of time so as to formulate knowledge of prognosis, which in many chronic conditions is imperfect, represents a simple type of investigation. There is need for more accurate work of this sort to formulate rules to forecast the patient's future. The question of the origin or cause of disease is of unusual importance to the clinical investigator and may require intricate and complicated studies. A catalogue of the varieties of studies which the clinical investigator may pursue will be long and of little value. It is more significant to realize that important original contributions are made which require only simple technical and clinical wisdom. To be sure, complicated apparatus and specialized knowledge may be needed to solve

problems arising at the bedside, but it seems that frequently the clinical investigator advances knowledge by discovery of the new with simple technic

Often the clinical investigator can study his problem by methods at his command, but he may find it necessary to seek out a particular technic or assistance from a wide variety of such divergent sources as botanic and sociological ones. The university investigators are apt to ask for advice from within one or another department of their own or other universities. There are, however, other sorts of institutions, such as industrial plants, where investigators seek, and more and more often will seek, advice and make progress by cooperation. The aim in these different sorts of laboratories is basically the same, namely, to search for truth regarding the laws of nature.

The present century has seen far-reaching organization and endowment of medical research, including units for the care of the patient, clinical investigation and teaching, which has influenced clinical medicine in important ways. Partly as a result of these developments, team work is much more general and prolific where before isolated efforts were the rule. This scheme of events has made it possible to undertake clinical investigation on a broader scale and to attack problems that formerly were impossible for one man to undertake alone. Artificial barriers between different fields of knowledge have handicapped science and art. This inherited tradition is fortunately being broken down, and one of the ways that should lead to the great advances of the future is the cooperative investigation of physicians, scientists and all types of scholars trained in different ways and in different sorts of institutions. For example, important knowledge has been obtained by the joint studies of engineers and physicians concerning the prevention of disease and for enhancing contentment in industry, and by chemist and clinician in the therapy of disease. Such cooperation when spontaneous is fruitful but when compelled may be sterile.

There are types of clinical investigation that demand organized study by institutions so that data can become available over many years and generations before final analysis is made, for example, creative work to determine the exact qualitative and quantitative influence of dietary factors alone or in combination with one another under varying climatic environment on the influence of thought and social life. The history of the people of this world could perhaps be written in terms of diet, as Zinsner has done in terms of epidemics. Initiative, progress, success and the happiness of a people tend to go hand in hand with an abundance of food and a good diet.

THE INVESTIGATION OF SOCIOLOGICAL CONDITIONS

The physician must have a deep interest in human beings, an interest in their economic and social structure as well as in their physical and psychic state. The clinical investigator is apt to be successful somewhat in proportion to his appreciation of the sick man as an individual. A considerable fraction of the successful care and treatment of patients, and undoubtedly the prevention of much illness, is to be identified with the proper consideration of the social, economic, psychological and allied factors. More attention by clinicians to the investigation of problems concerning such matters would be of great value, work requiring investigators trained in various fields pertaining to the medical, social and mental aspects of human beings. The diagnosis of

the person is too often neglected when diagnosis of the case is made in detail. Careful study and formulation and extension of knowledge concerning the medico-social aspects of cases is what is needed rather than leaving these matters to haphazard abilities or to individual interests. The field is a difficult one for reliable scientific study because it involves all the complications of human life. The science dealing with the relation between human behavior and health is in its infancy, and the progressive physician should attempt to advance medical knowledge in that direction as much as he has advanced that concerning organic disease within the past quarter century.

The medicosocial aspects of cases or the social component of medicine concern various fields of knowledge. Physicians for generations have been aware that the daily problems of life affect the health and happiness of individuals and have written on such topics. Even so they have not perhaps investigated these problems as often as have social case workers, psychologists, industrial experts, political scientists and clergymen. Although each has a contribution to make, the physician should do more, he, especially, is in a position to comprehend all aspects of an individual. He daily makes contacts with human beings whom the social environment has affected adversely, and to aid them he must know how readjustment can be made. Tact and personality play an important role, but an acquaintance with the stream of world thought and the actions of human beings are valuable when treating patients intensively and completely. The physician must understand what Smollett, in *Humphry Clinker*, first described well—indeed, it had scarcely been attempted before, namely, the different effects which the same scenes, persons and transactions have on different tempers. He must be a student of men and never forget the uniqueness of each human being if he is to be intelligent in the care of the sick. The many important matters that affect the checkered lot of mankind are not to be obtained in books only, but in the study of mankind. It is in the study of the fields of social science that the hope lies of making life better and happier, and the physician should do his share by increasing his investigative activities in this direction.

The late John Candler Cobb has defined social science as "the analysis and study of human relations and the forces that affect the development of civilization." Scientific methods applied with skill, concentration and proper facilities must be employed. The absence at present of definite "yard sticks" to measure factors to be studied is a handicap, but all sciences started with deductive reasoning from observation and developed first along the lines of qualitative methods and have gradually worked toward quantitative methods with the resultant tendency toward exactness. Psychology is essential to social science, for sociological and economic problems cannot be solved without psychologic data. Psychologists often give opinions, but quantitatively stated data are what is needed. The scientific method of approach to the problems of social science and the development of quantitative data will do much toward solving many difficulties with which the world finds itself at the present time and which, in turn, affect not only the doctor but the patient whom he must help.

Today the doctor may become a statesman in a wide field of activity and have great influential power. By and large he has been slow in studying the medico-social aspects of cases and applying such knowledge

skilfully, and now he finds that he should become acquainted with a variety of problems arising in social science. Medical economic problems of various sorts such as that creature "State Medicine," not yet satisfactorily defined or analyzed, and health insurance, as well as the relation of medicine and the doctor to modern sociological trends are matters requiring better knowledge, more thought and less passionate discussions. Perhaps a type of trained clinical investigator working at such problems from the physician's point of view will aid to bring divergent opinions into line by means of scientific methods with quantitative data.

Man in all his manifold relations will remain the center of thought and action for the physician, no matter whether he is or is not a clinical investigator.

A PHASE OF LIFE, EXEMPLIFIED BY BOOKS AND NATURAL HISTORY

In my introductory remarks I mentioned that it was an asset to the physician to broaden his outlook on life. I now plan to comment on a phase of life of value for anybody in spite of the fact that this may seem irrelevant. There are a myriad of ways by which the physician, whether a clinical investigator or not may broaden his mental horizon by activities outside the sphere of modern medicine. Specialization has been carried so far that it has caused a perverted view of life in some minds. A doctor should try to lead a complete life and not confine his thoughts to narrow fields. Indeed, it is often from other fields of knowledge than medicine that useful information is obtained to aid patients and to investigate their problems. The mind cannot always be consciously directed to definite ends. The ability to relax the tension of work is as important as the power of concentration, for the two processes combine in doing progressive work. Relaxation, when the mind follows its own bent, may be a significant period in life. Hobbies of various kinds, I believe, have their value to aid relaxation. They also may train the powers of observation. The collecting habit is common among medical men and they carry that spirit into their professional work.

Miscellaneous information acquired casually may not be of practical value, but it can serve for enrichment of thought. In these modern days of hurry there is a tendency to forget to reserve time for thought and relaxation. It seems to me that it is advantageous to see to it that there is time for what may be called informative extracurricular purposes throughout life. This time may not be measured in terms of accomplishment and certainly not in dollars, but it can be evaluated by some measure that is applicable to making life fuller and richer. As William Lyon Phelps has said, "the happiest person is the person who thinks the most interesting thoughts." Examples from every field and type of knowledge and experience could be cited showing that interests external to pure modern medicine can be of value to the physician. I will not only illustrate by remarks on books and natural history but also present a few thoughts on these subjects, because physicians often take a deep interest in such matters.

Books aid one to deal with the world of men. One may read for information, for refreshment or for enrichment by browsing at will. Literature and essays are a storehouse of the richest human interest. There is varied enjoyment and never-failing instruction regarding man. The works of Dickens and Stevenson and such essays as those of Montaigne, Sir John Lubbock and Hamilton Wright Mabie certainly help in the

understanding of patients. To read John Locke's essay "Some Thoughts Concerning Education" and come across the paragraphs concerning constipation, or "costiveness" as he calls it, allows one to wonder why the excellent rules regarding the treatment and prevention of this condition, which he so well set forth in the seventeenth century, are not practiced more often. If one then reads "A Dialogue between a Bilious Patient and a Physician," written by James Henry in 1838, one wishes one could persuade all human beings to grasp and follow the salient facts described in these books. Well known books must form the background of one's reading, but how fascinating it is to "discover" books off the "beaten path" that are appealing. Consider the anonymous "Essay on Laughter wherein are Displayed its Natural and Moral Causes with the Arts of Exciting it," published in London (translated from the French) in 1769, or consider the book by the apothecary Richard Browne, which appeared in 1729, entitled "A Mechanical Essay on the Effects of Singing, Music and Dancing on Human Bodies." The influence of these pleasures on health, folly and, as the authors remark, on "the cure of diseases," would be worthy perhaps of more modern scientific investigation than they have received. The essays on "The Art of Living Long," first published in Padua in 1558 and written by the Venetian Luigi Cornaro, who died in 1566 in his 103d year indicate, as Benjamin Franklin wrote, "against diseases known the strongest fence is the defensive virtue abstinence." The basic thoughts expressed by Cornaro regarding diet might have stimulated certain investigative studies by scientific methods long before they were undertaken, and even in recent years thoughts about these essays have suggested problems for clinical study.

Biography and history, including that concerning medicine, serve for orientation and perspective and is stimulating along many lines. There is always something corresponding in our own lives to be found in history. Whether one reads about the life of Syllius of Leyden (1614-1672) and learns how he first introduced bedside teaching, or about the life of a statesman or any other human being, one will become a better student of man from the experience.

Reading the works of past masters of medicine increases respect for accomplishments made without the aid of modern equipment or knowledge, and from them much useful information may be learned. Records made long ago may suggest investigations appropriate for today. It is remarkable how frequently one can find fragmentary and sometimes fairly complete information that has not been expanded or adequately utilized for generations. For example, Cartier's description of the cure of scurvy in the sixteenth century, Robert Boyle's comments on specific medicines in the seventeenth century, the experiences with cod liver oil and John Huxham's observations pertaining to blood clot retraction in the late eighteenth century, and the early references to the influence of diet on anemia. The history of the development of medical thought and of scientific discoveries can teach something about methods of thought and deduction and serve for the proper orientation of modern problems. To read about the keen observations leading to the early descriptions of disease excites admiration and can be a factor in arousing one to develop the use of one's own eyes. Books of many varieties on natural history can also help train one to observe, but one must learn to observe by studying nature, not only books.

The power to see straight is a rare gift. To see no more and no less than is actually before one, to see with one's reason as well as with one's perceptions—that is to be an observer and to read the book of nature aright. Many people may walk through fields and woods and see nothing, others may see every conceivable activity of plants, insects and birds. The physician who enjoys natural history will find that, like books, it broadens his horizon and permits interpretation into his professional career. Observe an azalea bush, which normally thrives in acid soil develop chlorosis, a condition leading to pale leaves and attributable to certain elements not being absorbed by the roots. Watching the "anemia" disappear on rendering the soil more acid, so the proper elements can be absorbed by the plant, can lead to observations concerning the effect of the hydrogen ion concentration of the intestinal contents on iron absorption in patients with anemia. Of course all biologic knowledge becomes of value to mankind and the clinical investigator can frequently be assisted by the biologist, but the pleasure and ideas he may receive by being fond of all that nature creates has its independent advantages.

To know the butterflies, their habits and instincts can give one enjoyment. The dietary habits of caterpillars and the influence of climatic factors on the development of butterflies can carry suggestions regarding the optimal mixtures of food for man. Some caterpillars are polyphagous and others will starve to death if they are not supplied with just what they want, which not infrequently is a single species or genus of plant. The size of a butterfly may vary with but slight changes in climate. For example, the brown-yellow-silver spotted butterflies of the genus *Argynnis* are prone to be smaller on the islands a few miles off the coast of Maine than on the neighboring mainland and thus cannot be attributed to want of food. As pointed out by Samuel H. Scudder nearly fifty years ago, the butterflies of America often have more broods in a year than the butterflies of Europe. The reverse is never true. There are very few butterflies common to the two continents. The painted lady (*Vanessa cardui*) butterfly is an example with two broods, and I believe occasionally three broods in America, but with never more than one brood in Europe. The comparison of the annual histories of similar European and American butterflies furnishes an instance of that intensity which characterizes all life in America. In Europe there is a tendency to proceed with less haste, in America we bend with nervous energy to our work and play. This aspect of our lives was correlated years ago with climatic differences, and in recent times studies by several men have shown how the more rapid and wider barometric oscillations in America can be correlated with certain features of the make-up of Americans.

Watching the changing distribution of insects locally or nationally permits one to reflect on similar phenomena referable to human disease. A most striking change in the distribution of two butterflies of this continent has taken place in the last seventy-five years. In 1860 the now common white cabbage butterfly, *Pieris rapae* was introduced from Europe. By 1871 it appeared all over New England and further introductions were made in various parts of this country. Now this insect is found in every part of North America and usually in great profusion. This imported butterfly has affected a native species, *Pieris oleracea*, which it

resembles, so that whereas it used to be very common in New England it is now exceedingly rare and found only in a few local mountainous regions.

CONCLUSION

In presenting some aspects of clinical investigation I have rambled from university education far afield across the domains of the clinician, the psychiatrist, the economist and other specialists to the world of insects. Even so I have not described a precise procedure for the training of a clinical investigator, because such a man cannot be made by any rule of thumb. The best sort of properly trained clinical investigator must be an able clinician, one with wide interests who understands human beings and can act wisely for all the multiple aspects of a given individual. He also must have an ardent desire to seek for knowledge by scientific methods and wish to carry the torch forward so that the next investigator will find it nearer the ultimate goal.

EXPLOSIVE GASES FORMED DURING ELECTROTRANSURETHRAL RESECTIONS

B. F. HAMBLETON, M.D.

R. W. LACKEY, Ph.D.

AND

R. E. VAN DUZEN, M.D.

DALLAS, TEXAS

Among the accidents that have been reported incident to the use of high frequency currents in transurethral prostatic resections are ruptures of the bladder attributable to explosions within the organ.¹ Doubtless similar explosions resulting only in damage to the bladder mucosa are not uncommon.²

The present investigation was undertaken with a view to determining whether the evolution of an explosive gas usually accompanies the use of high frequency currents in such resections and, if so, at what rate the gas is evolved, its composition, and how the danger of explosion may be minimized.

In experiments on a series of twelve dogs there was produced in every instance a gaseous mixture which, in the absence of oxygen from external sources, was not explosive but became highly explosive on the addition of the proper proportion of oxygen or air. When such mixtures were exposed directly to the arc from the resection apparatus they invariably exploded inside the bladder as well as in glass tubes constructed for the purpose. The violence of the explosion was sufficient to give a loud report when it took place in the exposed bladder, but in the healthy bladders of the dogs used no ruptures were produced. In one instance, 2 cc. of the gas mixed with air exploded in a pyrex tube inverted over water with such force that the tube was dislodged from the buret clamp in which it was held and shattered against the ceiling of the laboratory.

The idea that the gas might be produced by electrolysis at once presented itself, but when the rate at which it was evolved was measured it became evident that even were we dealing with a direct current, electrolysis would have been much slower with the amperage used. Under favorable conditions approximately

From the Department of Physiology, Baylor University College of Medicine.

¹ Kretschmer H. L. Intravesical Explosions as a Complication of Transurethral Electrosurgery. Report of Two Cases. J. A. M. A. 103: 1144 (Oct. 13) 1934.

² Cassuto A. J. urol. 22: 263 (Oct.) 1926.

1 cc of gas per second was obtained with a current not exceeding 500 milliamperes (By favorable conditions is meant that there is a considerable arcing.) Either cutting or coagulating current may be used effectively.

Since it appeared that the gases were derived from thermal decomposition of the tissues, the experiments were repeated on a smaller series of dogs, an ordinary heat cautery at high temperature being used for the resections. By this method a gaseous mixture with the same explosive properties was obtained. Quantitative differences in the composition of the mixture may be explained by differences in temperature produced by the use of the two types of instruments.

EXPERIMENT

The bladder in old male dogs under morphine and amylal anesthesia was exposed through a suprapubic incision. The cautery was introduced into the urethra through an incision in the perineum. A series of cuts was made into the prostate and the gas that passed into the bladder was drawn off from time to time by means of a needle thrust through the wall of the organ or by means of a cannula fastened in the dome of the bladder. In bladders that offered much resistance to distention the latter arrangement proved more satisfactory, as less gas was lost by escaping through the urethra.

Range of Percentage Values of Various Gases

Name of Gas	When Using High Frequency Current		When Using Heat Cautery	
	Low	High	Low	High
Carbon dioxide	62	14.9	12.8	14.2
Oxygen	2.0	5.1	0.2	1.6
Acetylene	1.0	2.2	2.1	2.6
Ethylene	Trace	1.0	2.4	12.8
Carbon monoxide	9.4	27.0	23.1	31.4
Hydrogen	37.6	53.9	29.0	43.5
Residual inert gas	12.3	17.3	14.2	17.7

The gas thus collected was analyzed for carbon dioxide, oxygen, acetylene, ethylene, higher sulphuric acid-soluble hydrocarbons, carbon monoxide and hydrogen in the order named. The absorbents used for the various gases were for carbon dioxide, a 33 per cent solution of potassium hydroxide, for oxygen, a solution obtained by mixing one volume of a 22 per cent solution of pyrogallol with five volumes of 60 per cent potassium hydroxide, for acetylene, a 20 per cent solution of mercuric cyanide in 2 normal sodium hydroxide, for ethylene, a solution made by dissolving 20 Gm of mercuric nitrate in 100 cc of 2 normal nitric acid and saturating this solution with sodium nitrate, for higher unsaturated hydrocarbons concentrated sulphuric acid, for carbon monoxide a solution prepared by the addition of one volume of ammonium hydroxide solution (specific gravity 0.91) to three volumes of a saturated solution of cuprous chloride in 25 per cent ammonium chloride.³ Hydrogen was determined by the use of a colloidal palladium solution stabilized with acacia and containing a small amount of sodium picrate.⁴

All of these gases, with the exception of the higher sulphuric acid-soluble hydrocarbons, were found to be present in varying proportions. In addition there remained a considerable amount of inert gas, presumably nitrogen, and a little more than a trace of some

gas or gases that yielded carbon dioxide on burning. The burning was accomplished by mixing the gas remaining after the analysis with some hydrogen and an excess of oxygen and then exploding the mixture.

The accompanying table shows the highest and lowest percentage values obtained from the analysis of various samples of gas from different dogs.

COMMENT

The unexpected presence of oxygen in the mixture containing such readily oxidizable gases as carbon monoxide, hydrogen and acetylene is understandable when it is recalled that the composition of the tissue being decomposed varies continuously during the cauterization. During the stages when an excess of oxygen is evolved the oxidizable gases are in all probability burned to carbon dioxide, which is always present in considerable amount. As the gases are formed they pass to the dome of the bladder and are thus removed from the field of action, so that combustible gases evolved during other stages of the decomposition become mixed with the oxygen after having passed from the vicinity of the cautery. This does not necessarily mean that the gas evolved during the early stages of the resection differs in any regular way in composition from that evolved in the final stages, since the cautery may be brought into contact with some fresh tissue as well as partly decomposed tissue up to the time the resection is completed. It is also possible that in some instances the oxygen is in part of atmospheric origin, since it is difficult to be absolutely certain of complete exclusion of air. However, the higher ratio of oxygen to inert gas present in some of the gaseous mixtures indicates that the oxygen is evolved by the action of the cautery on the tissues.

The surprisingly rapid rate at which highly inflammable gases may be evolved in the use of high frequency currents for transurethral resections emphasizes the necessity of caution to prevent the occurrence of serious accidents. Since a small volume of gas mixed with air is sufficient to produce an explosion of great violence, a mere washing out after each series of cuts cannot be considered an adequate safeguard unless the entrance of air is rigidly prevented. In cases of dilated or atonic bladders or when a diverticulum is present, accumulated gases may not be removed even by careful washing. The diverse character of the gases in the mixture precludes the possibility of their removal by an absorbent. If a large amount of air or gas collects in the bladder, as shown by a large bubble, this should be aspirated by inserting a ureteral catheter into the bubble before further cutting or coagulation is done. When the patient is placed in the Trendelenburg position the bubble is brought closer to the area to be coagulated and the danger of explosion is increased, as explosion does not occur unless the arc comes in direct contact with the gas.

SUMMARY

A mixture of inflammable gases is produced when high frequency currents are used for transurethral resections.

Similar gaseous mixtures have been obtained by the use of the heat cautery.

The gases are produced by the thermal decomposition of the tissues.

The composition of the gaseous mixture has been determined, and it has been shown that oxygen from external sources is necessary to render the gas explosive.

ABDOMINAL PAIN AS A SYMPTOM
OF DISEASE OF THE BRAINI S WECHSLER, MD
NEW YORK

Abdominal pain is not generally associated with disease of the brain, when gastric distress does occur in tumors or other cerebral conditions it is either ignored or casually explained on the basis of the associated nausea and vomiting. Occasionally, if the pain is sufficiently severe, gastro-intestinal or gallbladder disease is thought of, as is also the possibility that the cerebral condition is secondary or metastatic in nature. The very rare occurrence of abdominal pain as a symptom of tumors of the fourth ventricle is not generally referred to (Ernest Sachs some time ago reported one case) or regarded as clinically important, and when fleeting thought is given to the fact the opinion ventured is that it may have something to do with the vagus. Many years ago I saw a boy (case 1) with a frontal epidural abscess who presented a clinical picture of acute appendicitis. He was operated on, a normal appendix was removed, and fortunately he recovered when the abscess was evacuated by the brain surgeon. Several years later I saw a girl, aged 16 years, with an intrapontile tumor that extended to the midbrain and possibly involved the hypothalamic region, who complained of abdominal pain. The first symptom was urinary retention requiring catheterization, but she also had definite abdominal pain not associated with distention of the bladder. About the same time a young man with hemangioblastoma of the cerebellum came under my observation. The clinical history, which extended over a period of years, was punctuated by recurrent attacks of abdominal pain. Because of negative results of the general medical examination the patient's complaints were looked on as psychoneurotic. He subsequently died of the cerebellar tumor, which had invaded the fourth ventricle.

These three cases led to the question whether disease of the brain may not in some way affect the visceral efferent pathways anywhere from the cortex through the hypothalamus to the vagus region in such a way as to manifest itself on occasion in the form of abdominal pain. What is known as abdominal migraine, a rather ill defined clinical syndrome, also came to mind, and the question arose as to the possible correlation of the abdominal symptoms with what is regarded as a cerebral condition. The occurrence of abdominal pain either as an epileptic aura or following a convulsive attack or as the equivalent of a convulsion presented itself for consideration. So did the rare occurrence of morbid hunger in brain tumors. Still another question was raised by the occasional presence of abdominal pain, definitely not on the basis of radicular involvement, in both acute and chronic encephalitis. The fact demonstrated by Cushing that solution of pituitary injected into the ventricles gives rise to gastric hypermotility, pylorospasm and reverse peristalsis lent further plausibility to the assumption that abdominal pain may be a symptom of disease of the brain. The occurrence of peptic ulcer in cortical lesions, a fact that has received considerable attention in recent years though known practically since the days of Rokitsansky, naturally also served as both question and answer to the problem of abdominal pain in disease of the brain, despite the fact that what is here considered is merely pain and not a

pathologic condition of the gastro-intestinal tract. Finally arose the question whether the abdominal pain that the "neurotic" often complains of, or the intestinal peristalsis that manifests itself in diarrhea and the reverse peristalsis that expresses itself in vomiting, or the inhibition of gastric and intestinal peristalsis, are not in effect the result of disturbed cerebral physiology rather than what is with ill concealed contempt designated as "bellyaching."

All these facts, to be discussed presently at greater length, which are further supported by the experimental production of intussusception after ablation of the premotor cortex, justify the assertion that abdominal pain, without demonstrable intra-abdominal pathologic changes, may be regarded as a symptom of disease of the brain. That it is not rare can be inferred from the fact that in a comparatively short time I have been able to gather sixteen cases. Indeed, special attention revealed a number within a very few months. However, whether or not the symptom is common or rare is not nearly so important as that it occurs and that it is generally overlooked or wrongly interpreted. In any case it demands explanation. The following cases, given here in the briefest outline, illustrate the occurrence of the symptoms.

REPORT OF CASES

CASE 1—A boy, aged 10 years, seen by me in consultation two weeks after an operation for "acute appendicitis," had had a moderate degree of fever for several days, complained of severe frontal headache vomited, and was going from drowsiness into stupor. Two weeks before the boy began to complain of abdominal pain. He vomited a few times, not after meals, and had fever. The blood showed leukocytosis. Based on these observations, despite the absence of abdominal rigidity, the surgeon made the diagnosis of appendicitis operated on the boy, and found a normal appendix. The patient made an uneventful operative recovery, but after ten days he began to have headache, to vomit once more and to go into stupor. When seen by me he had beginning papilledema and marked tenderness to percussion over the frontal bone and the deep reflexes were bilaterally hyperactive. The presence of a comparatively recent scar on the forehead elicited the information that while playing the boy had fallen on his face a few weeks earlier and cut his forehead but he had concealed the fact from his parents until he came home in the evening. Apparently he suffered few after-effects the headaches fever, abdominal pain, vomiting and leukocytosis not appearing until two weeks later. A roentgenogram of the skull showed a fissure fracture of the frontal bone. Trephine exploration led to the evacuation of a frontal epidural abscess and to recovery. The abscess was fairly large and had compressed the frontal poles.

CASE 2—L. Y., a woman, aged 20, was admitted to the Montefiore Hospital because of abdominal cramps and generalized convulsions. The former, mainly localized in the epigastrium and right upper and lower quadrants had lasted fairly continuously for three years. After repeated examinations at another hospital, it was decided that she had "chronic appendicitis and hysteria," and she was treated without relief. The convulsions appeared six months before admission to the hospital and gradually increased in frequency until they occurred several times a day. They were characterized by sucking movements of the lips, tonic spasms of the right upper extremity and groping of the hand, and were followed by a period of disorientation. She vomited frequently. She had old-standing bilateral choked disk with secondary optic atrophy, which had progressed to complete blindness. She died four days after admission to the hospital. At necropsy a large infiltrating hemorrhagic tumor of the right temporal lobe and hippocampus, invading the putamen and globus pallidus, was found.

CASE 3—C. I., a man, aged 36, had had generalized convulsions for ten years, apparently controlled by medication. Ten days before admission to the Montefiore Hospital he began to vomit and to complain of epigastric pain. He gradually

became stuporous and died. The neurologic examination gave few and inconclusive results. The fundi were normal. The laboratory data, except for an increase of lymphocytes (20 on the first and 10 on the second tap) in the spinal fluid, were negative. The temperature rose to 103 F. The patient died, and at necropsy an oligodendroglioma was found infiltrating the right frontal lobe up to the parietal.

CASE 4—M. D., a man aged 56, admitted to the Montefiore Hospital in 1933 had had seizures, headaches and impairment of vision for a year and a half and for the last six months pains in the right side of the abdomen at times accompanied by vomiting. He became impotent and lost sexual desire five years before admission to the hospital. The petit mal attacks consisted of perception of bad odors, pallor, and momentary loss of consciousness. Examination showed scanty facial, axillary and bodily hair of female distribution, bilateral optic atrophy, constricted visual fields, a basal metabolic rate of minus 17, marked destruction of the sella turcica, negative serologic changes and a negative gastro intestinal series of films. The diagnosis of pituitary tumor was made, operation was advised but refused, and the patient was discharged.

CASE 5—L. I., a man aged 21 seen at the Jewish Hospital Brooklyn in May 1933 following right frontal sinusitis had a right frontal epidural abscess, which was evacuated and followed by recovery. In November 1933 he was readmitted in coma and a right frontal lobe abscess was evacuated. After five weeks he was discharged, only to be again admitted in February 1934. This time a right temporal lobe abscess was evacuated. He remained in the hospital till May at which time he was discharged fully recovered. In addition to headaches, convulsions and focal signs he suffered throughout his stay in the hospital from attacks of right sided abdominal pain, accompanied by nausea and hiccups. Abdominal examination did not account for the pain. As his cerebral condition cleared up the abdominal pains subsided.

CASE 6—A. G., a youth aged 15, was admitted to the Jewish Hospital, April 27, 1934 because of headache, vomiting and convulsions. He had fallen and struck his head March 11 but was not unconscious. April 6 he began to have generalized convulsions. From April 13 to April 27 he suffered generalized abdominal pains. Examination showed bilateral papilledema and left homonymous hemianopia. Evacuation of a right temporal lobe abscess resulted in complete recovery.

CASE 7—A. A., a woman aged 41 complained of headaches and pains in the back of the eyes for ten weeks and pains in the left lower quadrant, worse at night, for six weeks. Except for bilateral choked disk with retinal hemorrhages, she showed no neurologic signs. A ventriculogram revealed a dilated ventricular system, including the fourth, namely, marked internal hydrocephalus. Suboccipital exploration failed to show a tumor. The patient was discharged unimproved and entered another hospital, where another operation was performed and the diagnosis of arachnitis blocking the ventricular foramina was made.

CASE 8—H., a woman, aged 46, admitted to the Neurological Institute, complained of stomach trouble with cramps and vomiting, occipital headache, unsteadiness, and disturbance of vision. The history was that she had been suffering occipital headaches for fourteen years. At the same time she had blurring of vision and unsteadiness in walking. During this period she had attacks of cramping pains in the abdomen which increased in severity for four or five days and decreased for a few days, only to recur again and again. The attacks were accompanied by nausea and vomiting. The presence among other conditions of left homonymous hemianopia pointed to a right-sided lesion, and at operation a meningioma overlying the right occipital lobe was removed.

CASE 9—W. K., a male, admitted to the Neurological Institute, Oct. 1, 1934, because of pain in the eyes and the stomach of about one month's duration awoke one night with severe pain in both eyes and very severe abdominal cramps unaccompanied by nausea or vomiting. The pains lasted about one hour and recurred every night. Abdominal examination was negative. The neurologic changes consisted of left-sided pyramidal tract signs and blurring of the margins of the disks.

Roentgenograms of the skull showed a calcified mass in the inferior portion of the right occipital lobe with characteristic parallel, convoluted arrangements seen in venous angioma of the brain. The patient was not operated on and was discharged ten days after admission.

CASE 10—J. H., a man, aged 36 admitted to the Neurological Institute in June 1934, complained of headache, difficulty in walking, spots before the eyes, and abdominal pains and vomiting. He had been operated on in August 1925 and again in January 1928 for a left cerebellar cyst. For five months before the last admission he had been suffering from severe pains in the abdomen and vomiting. Roentgen examination showed no evidence of pathologic changes either in the stomach or in the intestine. Neurologic examination confirmed the recurrence of the tumor in the left lobe of the cerebellum.

CASE 11—G. T., a girl, aged 19 years was admitted to the Neurological Institute with a two-year history of frontal headache, vomiting, somnolence and impairment of vision. For one year she had had occasional attacks of abdominal pain. Reduction of visual acuity, bilateral optic atrophy, temporal hemianopia in one eye and roentgen evidence pointed to a buccal neural pouch tumor. She was operated on and a cyst in the suspected region was found and drained. During her stay in the hospital both before and after the operation the patient had on three or four separate occasions severe lancinating abdominal pains with tenderness. At one time the diagnosis of appendicitis was made. Examination failed to reveal pathologic changes of the abdomen.

CASE 12—C. O., a girl, aged 16 years admitted to the Neurological Institute complained of headache, drowsiness, vomiting, abdominal pain and weakness of the left side of the body for the past month. Examination showed left hemiparesis, papilledema with retinal hemorrhages and roentgen evidence of increased intracranial pressure. At operation an infiltrating tumor beginning in the right frontal lobe and extending backward to the parietotemporal was found. Pathologically it proved to be a medulloblastoma. The abdominal pains that persisted after operation consisted of sharp cramps in the right lower and upper quadrants. The pains had no relation to meals.

CASE 13—R. W., a woman aged 40 admitted to the institute complained of vomiting, headache, unsteadiness, and awkwardness of the right arm. For several months she also had abdominal colic. Examination showed cerebellar ataxia, nystagmus and bilateral choked disk. A ventriculogram pointed to a tumor of the posterior fossa. At operation a right cerebellar tumor, later reported as an "unclassified glioma," was removed. The abdominal pains, which persisted after the operation consisted of gnawing in the right upper and lower quadrants and of colic-like spasms, which kept recurring. There were no associated gastro-intestinal symptoms. Careful examination ruled out suspected gallbladder disease and other abdominal conditions.

CASE 14—F. F., a woman, aged 48, on admission to the institute complained chiefly of frontal headache, vomiting, dizziness and mental confusion of three months' duration. For two years she had had recurrent abdominal pain. Examination showed bilateral papilledema, left lower facial weakness and increased deep reflexes on the left side. A roentgenogram of the skull showed a right frontal, parasagittal tumor. At operation an infiltrating tumor, later proved to be an astrocytoma, was found in the frontal lobe posteriorly and parasagittally. The abdominal pains both before and after the operation which had no relation to meals consisted of cramps near the umbilicus. Because she had been jaundiced sometime before the operation, roentgen and other examinations were made and no gallbladder disease was found. Further examination at the hospital failed to reveal the cause of the abdominal pains.

COMMENT

In trying to explain the occurrence of abdominal pain on the basis of brain lesions, one is confronted with the difficulty that little is as yet known of the anatomy and physiology of the visceral efferent or autonomic pathways of the brain. Nor is it possible on the basis of pathologic lesions alone to localize this symptom anatomically or to correlate a particular region with the

PAIN AS A SYMPTOM—WECISLER

649

production or mediation of the pain. While six of the cases herein recorded (and if the tumor in the region of the pituitary, which impinged on the frontal lobes, included there were seven) involved the frontal lobes, two each were in the temporal and occipital lobes and three were cerebellar or in the posterior fossa. Experimental evidence points more or less to the premotor area, but there is much to be said for an interbrain or hypothalamic localization, and arguments could be adduced in favor of the vagus region.

Although I am not here concerned with the question of neurogenic erosions² or the production of gastric and duodenal ulcers³ and perforations by cerebral lesions, their occurrence bears on the problem of abdominal pain. Cushing⁴ correlated the occurrence of peptic ulcer with lesions of the interbrain region, and his experimental demonstration that gastric hypermotility, pylorospasm and reverse peristalsis can be induced by the intraventricular injection of solution of pituitary lends plausibility to such a view. It is noteworthy, however, that, if one excludes the two cases of inahugnant hypertension, which do not help in the localization, six of his remaining nine cases were cerebellar or posterior fossa tumors, one was parietal only one was in the third ventricle, and the other was an olfactory groove meningioma. If, therefore, localization should be attempted on the basis of his cases, one might be compelled to look in the vagus region. None the less there is a great deal to be said for the hypothalamus⁵ and its numerous visceral autonomic structures. It may be, of course that lesions in all three regions are capable of producing abdominal pain and that a discharge may be set up in the autonomic portion of the cerebral cortex, wherever that may be, or the hypothalamic or vagus region. Most of the evidence so far adduced points, however, to the cortex.

As far back as 1876 Bochefontaine⁶ showed that stimulation of the sigmoid gyrus in the dog resulted in peristaltic contraction of the pylorus and sometimes inhibited rhythmic contractions of the stomach. Other experimenters showed that cortical stimulation may either set up or inhibit peristalsis and concluded that the cortex actually has an inhibiting influence. This was deduced from the fact that stimulation of the vagus does not induce peristalsis if the cortical connections are intact but does if the cortex is ablated or if sections are made at various levels above the vagus. The occasional occurrence of diarrhea in the case of removal of cortical inhibition. But the more recent work of Watts⁷ and of Watts and Fulton⁸ is not only highly interesting but probably points to the explanation of abdominal pain in brain lesions. They reported the spontaneous occurrence of intussusception in monkeys after ablation of the cortex and showed that stimulation of the premotor cortex induced peristalsis and in two cases intussusception, that occasionally stimulation of the frontal and postcentral convolutions

induced peristalsis, and that sectioning of the vagi prevented the occurrence of intussusception and induced only slight peristalsis. They concluded that the cerebral cortex contains autonomic representation, both inhibitory and excitatory. They stated that the probable pathways are from the cortex to the hypothalamus, the red nucleus, the substantia nigra and the vagus. That the pathway is by way of the vagus was inferred from failure of cortical stimulation to induce peristalsis if the vagi are cut. That the hypothalamic region is another center was deduced from failure to cause peristalsis on stimulation of the lateral margins of the infundibulum if dial or barbiturates were given, these drugs being presumed to affect the hypothalamic nuclei.

That pain can occur as an epileptic aura, as an equivalent of a convulsion or as a postconvulsive phenomenon is a well known clinical fact. Penfield and Gage⁹ have shown that stimulation of the cortical area 7a caused pain in the right lower quadrant of the abdomen and elicited an epileptic attack. They concluded, as did Watts and Fulton in the case of monkeys, that there is in man sensory autonomic representation for the gastro-intestinal tract in the cerebral cortex. Watts and Frazier¹⁰ also state that a neurogenic discharge may manifest itself through abnormally vigorous movements of the gastro-intestinal musculature and that the discharge comes from the autonomic portion of the cerebral cortex, although they cannot say just what part of the cortex it is. In any case, cortical autonomic epilepsy expresses itself in nausea, vomiting and gastric distress. Fulton suggests that morbid hunger may be due to excessive motility of the stomach. Spiller¹¹ once reported the occurrence of morbid hunger in a patient with gloma of the pons and again (quoted by Watts) in the case of a large meningioma of the frontal lobe.

Migraine expressing itself in recurrent crises of abdominal pain, though neither common nor well defined, may possibly be the expression of fleeting cerebral pathologic changes. This view is fortified by the opinion commonly held that some cases of migraine are due to anaphylaxis and by the fact that the brain can react focally to sensitization. I have seen such cases and so have other observers. Cassirer¹² mentioned edema, and E. Flatau described abdominal pains, hyperperistalsis and diarrhea in migraine. Oppenheim¹³ cited cases of paroxysmal abdominal pain in children with migraine as equivalents lasting several hours and cited Moebius, who spoke of gastrocnysis, namely, paroxysmal hypersecretion of hydrochloric acid as a form of migraine. The view that abdominal pain may be an expression of paroxysmal headache due to local pathologic changes of the brain does not conflict with the opposite view that the pathologic changes of the brain or hepatic disturbances may be the result of gastric While encephalitis, because of its dissemination, cannot be lightly invoked as a basis for cerebral localization, it is a brain disease, and, if abdominal pain can be shown to occur as one of its manifestations, the inference is justified that the pain is cerebral in origin. I am not unmindful of the fact that radicular pains in the

lower thoracic region can, as in tabes for instance, simulate abdominal syndromes, but in the main I believe that the glib ascription of abdominal pain to root involvement is not justified. The observation may be true, perhaps, in the myeloradicular types of encephalitis but does not hold for those cases in which the infection is more or less limited to the brain, midbrain and brain stem. Certainly no definite radicular distribution has been demonstrated in those cases. But, what is more important, I have seen instances of abdominal pain in encephalitis when there was no suspicion whatever of radiculitis and can cite at least two cases of dystonia, definitely on the basis of encephalitis, which were characterized by constant and severe abdominal pains that hardly yielded even to morphine, and by intractable vomiting that was the expression of reverse peristalsis. That dystonia, too, has an underlying disseminated pathologic condition not lending itself to special correlation of structure with function does not invalidate the conclusions that the abdominal pain is in fact the result of disease of the brain. In any case both acute and chronic encephalitis affect those regions, namely, the cortex, interbrain and bulb (vagus), which may possibly have to do with the production of abdominal pain, even though the virus has a predilection for the hypothalamic and midbrain regions. The inference is also justified that cardiospasm and esophagospasm may be due to hypothalamic involvement, it is known to occur in impairment of function of the vagus.

While hysterical or so-called psychogenic abdominal pains are generally vague and diffuse, they are not infrequently severe and localized sufficiently to simulate abdominal syndromes of one kind or another. It is not at all either a novel or an uncommon experience to come across hysterical patients who have been operated on one or more times for nonexistent gastric ulcers, gall-bladder disease, appendicitis and the like. The common explanation that hysterical pains are psychogenic in nature and the psychoanalytic one that they are conversion symptoms though to a large extent true and psychologically satisfactory, ultimately beg the whole question. To say that the hysterical pains are of no significance is obviously untrue and to dismiss the patient with the statement that he is "bellyaching" is bad diagnosis and worse practice. The fact is that the patient does have a belly ache and it is just as real to him or to her as if it were caused by renal or gall-bladder colic, for instance. It may well be that actual disturbance of cerebral functioning, secondary to psychic emotional stimuli, is the underlying factor in the production of abdominal pains. In this sense psychogenesis merges into physiogenesis or neurogenesis. That sudden fright, for instance, can induce intestinal peristalsis and lead to diarrhea or contraction of the stomach wall and precipitate vomiting is a well known clinical fact. It may be debatable whether one is dealing here with cortical stimulation or inhibition, but it is hardly to be doubted that one is dealing with a cerebral process probably involving in the circuit the cortex, the hypothalamus and the vagus. Since it has been shown that abdominal pain can and does occur on stimulation or irritation or pathologic involvement of the cortex and possibly of other regions, it is quite probable that the hysterical abdominal pain is the expression of a psychophysiogenic process and that the hysterical patient suffers neurogenic cerebral pain. In any case cerebral vomiting and pain, and this may be equally true in cases in which there are demonstrable pathologic changes, are not altogether unrelated.

CONCLUSIONS

From what has been said so far, it may be set down as a clinical fact that abdominal pain occasionally occurs in disease of the brain and that it may be regarded as one of its manifestations. The probability is that it occurs more frequently than appears from casual observation and that special attention will bring to light a greater number of cases, particularly in tumors and other expanding lesions of the brain. It has been shown that it can occur in the convulsive state, in migraine, in encephalitis, in hysteria, and under experimental conditions. The present paper deals with expanding lesions, which are of such great importance to the neurologist and neurosurgeon. Most of the evidence presented points to the cortex and possibly to the frontal, more particularly the premotor, area as the source of neurogenic abdominal pains and indicates that the cortex contains visceral autonomic representation. But there is also evidence to show that the hypothalamus and possibly the vagus region may be responsible for the abdominal pains, and that if the cortex is the source of the pain it is mediated by way of the lower levels or centers. The symptom, therefore, cannot be said to have localizing value, though it may point to the frontal part of the brain. Both the observation and the proffered explanation may have clinical significance alike for the neurologist and for the internist and abdominal surgeon.

SYSTEMIC THRUSH IN CHILDHOOD

FREDERIC W. SCHLUTZ, M.D.
CHICAGO

Since the days of Virchow a group of diseases which primarily affect the skin and its appendages have been designated as mycoses. The etiologic factor in these disorders seems to be plant agencies, particularly fungi.

Thrush is one of these diseases and plays a principal role in the mycotic disorders of childhood. It differs from other fungoid infections in that, in addition to the skin the mucous membrane and some of the internal organs may be affected.

Contrary to general opinion, thrush is not caused by only one species of fungus, the so-called thrush fungus or *Oidium albicans* (Robin). According to Castellani¹ it may be caused by a number of different fungi, some of which are botanically far apart from one another, belonging to separate species, genera and families. The fungi belong to the large group of thallophytes, plant organisms that are without chlorophyll, that do not assimilate carbon dioxide and that are dependent on a saprophytic or parasitic existence.

There are three different groups of the mycoid fungi, molds, yeast forms or sporothrix, and dermatophytes. It is under the last named group that thrush as commonly seen in infants and children is classified.

Two principal types of thrush can be distinguished clinically: the white or gray-white type that is extremely common and the yellow or yellow-brownish type of rarer occurrence.

The dermatophytes are distinctly dermatophilic and have a predilection for the carotene-containing epi-

From the Department of Pediatrics, University of Chicago.

dermal layers and the hair and nails. The dermatophytes require very little nitrogen and make little demand on their environment for subsistence.

The capacity of most dermatophytes to exist or live is exceptionally good. They are very resistant to physical conditions, such as heat, cold, dryness and many chemical substances. An explanation of this resistance is probably found in the thickened membrane which supports the spore forms.

Dermatophytes require but little oxygen and many forms are anaerobic. They have an excellent buffer action, which gives them the capacity of retaining a favorable reaction for a long time and of counteracting unfavorable ones rapidly. They tend to form alkali and have a marked tendency to cause fermentation.

Lipoids permit the fungi to enter into a slight lipid coating of the skin. Trypsin-like ferments aid in the solution of the surrounding skin, and the resulting products of alkaline breakdown cause the moderate inflammation which is characteristic of these lesions.

The affected skin manifests certain defense reactions, one of them being a progressive keratinization and lamellation, particularly of the horny layers of skin, such as the nails and nail beds.

Thrush belongs to a group of mycoses which not only affect the skin but may also affect the mucous membranes and the internal organs and in rare cases cause general sepsis.

The most common form of thrush occurs in the mouth of young infants, particularly if they are poorly nourished. Ordinarily the disorder is due to a mold and readily yields to simple forms of treatment. It can, however, occasionally show formidable symptoms and present a clinical picture of an infection which for tenacity and baffling resistance to all forms of therapy hardly has an equal. If a chronic form of general sepsis develops, it almost uniformly leads to a fatal termination.

Beginning with lesions about the mouth there are extensive angina, involvement of the entire gastro-intestinal tract and lesions about the anus and, in the female, about the genital region. Often there is more or less involvement of the lungs. Of the abdominal organs the kidneys and liver are chiefly invaded.

Exceedingly chronic lesions develop on the skin involving particularly the extremities and the nails and nail beds and appearing in fairly large, isolated patches on the trunk.

The lesions are rather dry with considerable tendency to scaling and crusting. There is little itching except when interdigital spaces are invaded. At no time is there a severe inflammatory reaction and even when there is evidence of extensive sepsis, the disorder may be afebrile unless acute pulmonary inflammation is a complication.

In practically all the lesions, massive formation of mycelia and spores can be demonstrated. Small vesicles are often found in the desquamating portions of the lesions. The organisms are grown easily, especially on solid mediums.

Thrush is not contagious and arises only when conditions favorable to its development are present.

Czerny² expressed the view that fungi are present in the mouth of every infant with thrush. Epstein³ found that thrush is not found in the infant's mouth until the fifth day and is rarely found after the second year.

Thrush is not confined to young infants, as it may occur at all ages. It is not known why the organism can remain latent and harmless and then suddenly become pathogenic.

In latent thrush not only the mouth but the entire digestive tract may be involved. The organisms are apparently not destroyed by intestinal secretions. In all cases of thrush the infection probably originates in the mouth.

Thrush generally remains a localized superficial disease and seldom becomes an infection of the blood stream, but it may involve the skin and internal organs extensively and present all the manifestations of general sepsis.

Moro⁴ expressed the belief that sepsis due to thrush is more common than is generally believed. Generalized cutaneous manifestations of thrush in infants were first reported by Beck⁵ and by Ibrahim⁶. Since then occasional additional cases have been reported in the pediatric and dermatologic literature.

Still more rare are the generalized septic forms, which generally end fatally. Heubner⁷ reported such a case in 1903 in a girl, aged 16 months. The entire visible mucous membrane of the mouth, throat and pharynx was covered with a yellowish, dry exudate which resembled a diphtheritic membrane but proved to be thrush. Fatal termination of the case was preceded by dyspnea and severe symptoms of sepsis. Extensive pulmonary and renal involvement was found at autopsy. Typical organisms were recovered from all the lesions.

A similar case in an infant of 6 months was reported by Schamberg⁸. In addition to the oral lesions, there were extensive cutaneous lesions and death occurred soon.

A case of thrush in an infant 5 months of age showing polyarthritis and extensive gastro-intestinal involvement was mentioned by Goldring⁹. This patient recovered. A twin sister also had generalized thrush but no symptoms referable to the joints.

Christison¹⁰ reported the condition in an older child. The first symptoms appeared when the child was 2 years old and the entire duration of the disease was three years. Extensive cutaneous lesions developed, especially about the face, scalp and nails and finally there was massive pulmonary involvement. Extreme weakness and emaciation preceded the fatal termination.

During twenty-five years of pediatric practice I have seen five patients with generalized systemic thrush, all showing very unusual symptoms. Four of these cases are reported here, the fifth case was the one reported by Dr Christison. The patient had been under my care for about one year.

REPORT OF CASES

CASE 1.—B. G., a girl, aged 4 months, I saw first in October 1913. The complaint was excessive drooling, eruptions about the mouth, vulva and rectum and white patches in the mouth. She had been in fairly good health up to the age of 5 months. She had been breast fed for one month and then artificially fed with mixtures of dilute cow's milk. The gain in weight had been good until the third month. After that there were gastro-intestinal disturbances, persistent loss in weight and gen-

eral decline. The drooling and eruptions had been present for about two weeks before I saw the infant.

Eruptions resembling impetiginous lesions were present in the angles of the mouth and on the right cheek. Lesions similar to those seen about the mouth were found adjacent to the rectum and a few on the labia majora.

A moderate degree of diarrhea was present. The temperature was not elevated. There was paronychia of the thumb and middle finger of the right hand. The mucous membranes of the lips, the entire buccal surfaces and the anterior portion of the tongue were covered with yellowish white membranous patches. There was no fetor. The membranes could not be detached and there were no bleeding surfaces. Diphtheria was thought of but both smear and culture proved to be negative. Scrapings of the membrane showed numerous mycelia and spores of *Oidium albicans*. Scrapings from all the superficial cutaneous lesions, including the paronychia, showed the same organism and established the diagnosis.

Within a few days the entire mouth and throat, including the tonsils and hard and soft palate, were covered with a thick, furry, whitish membrane. There was excessive drooling and considerable difficulty in breathing.

Food was persistently refused and a moderate diarrhea with mucous stools continued. Simultaneously with the onset of fever, pneumonic inflammation developed in both lungs, presumably due to extension of the thrush. The infant succumbed three weeks after the onset of the illness and the first evidences of the infection. Autopsy was not permitted.

No form of treatment either local or systemic inhibited or influenced in the least degree the progressive development of the disease.

CASES 2 (M S) and 3 (S S).—The next two cases involved two sisters, M S, aged 4 years and 9 months, and S S, aged 6 years. These children were admitted to the University Hospital in July 1924 with identical complaints of generalized alopecia, generalized impetigo and malnutrition.

The father was a tanner but had never had any cutaneous disease. Two brothers, one aged 13 years, the other 3 years, have been well and free from the disorder exhibited by the sisters.

Both girls were born at full term, had normal weight, were breast fed for a year and developed normally in every respect until they were a year old. Both had pertussis during the first year and the older child had a mild attack of varicella during the fourth year of life.

In the older child, cutaneous lesions appeared when she was 3 months old, first in the form of a nail-sized crust over the occiput. Similar crusts developed on both cheeks. These were diagnosed as eczema and cleared up under treatment. A few weeks later similar lesions appeared about the corners of the mouth.

The lesions had a red slightly inflammatory base, covered with dry scaly crusts. The removal of these left a raw red, slightly weeping area over which the dry, scaly crusts rapidly reformed. Lesions have persisted about the mouth and its immediate neighborhood up to the present time.

When she was 18 months old, the finger-nails of both hands became involved the infection clearing up at times with loss of the nails and then reappearing. After the second year, lesions similar to those on the face spread over the dorsal surfaces of both feet, the heels and the surfaces of both elbows and knees. There were practically no lesions on the trunk and the vulva and rectum were free.

When the child was 3 years old an attending physician diagnosed the condition as tinea. Under treatment all the lesions cleared up except those about the mouth, only to reappear again in three months over all the previously affected body surfaces.

Subsequently a diagnosis of impetigo was made, but no form of treatment seemed to influence or relieve the disorder.

The cutaneous condition continued practically unchanged from the time of its initial appearance to the time of admission to the hospital, a period of nearly six years. During that entire period there was very little gastro-intestinal disturbance and the child was relatively free from respiratory disease.

Two striking features developed during the course of the disease. There was marked retardation of the child's growth, especially in height, leading to definite dwarfing but without

any impairment of the intellect, and complete alopecia, which first developed when she was 4 years old. Up to the time of admission, the hairs of the scalp, eyebrows and lashes had shed and reappeared four successive times, but there had been no regrowth of hair for over a year and there was every indication that the baldness was permanent.

The history of the younger child previous to admission was similar to that of the older sister. Cutaneous eruptions about the mouth, eyes and ears and on the feet, legs and elbows, over the sacrum and on the nails of both hands and feet have existed for a period of three and one-half years. There has been considerable itching of the eruptions about the mouth and eyes. Troublesome anorexia has existed for nearly three years and she has shown marked undernutrition for about one year. As in the older child, there has been considerable dwarfing.

The eruption first began when the child was a year old and dry, itching, scaly eruptions on a reddish base developed about the corners of the mouth and eyes. The diagnosis, treatment and course of the lesions and their character and general distribution were almost identical with those of the older sister. The hair did not begin to fall out until a year previous to admission and grew out once or twice, but there had also been complete and apparently permanent baldness with loss of eye brows and lashes for four months preceding her entrance to the hospital.

At the time of admission the striking feature in both cases was the marked dwarfing. They had the stature and appearance of infants of 8 months and a year, respectively, but the intellect and mental development as evidenced by their speech and actions were those of children 4 and 6 years old. The complete baldness and loss of all hair about the eyes, the marked pallor and transparency of the skin, and the marked state of undernutrition and tissue atony also were striking features. They were able to sit up but had not walked for many months.

Considerable tendency to looseness of the bowels has existed during the past year. Infections of the upper respiratory tract have been infrequent. The mouth, nose, throat and lungs of both children were free from any evidence of infection at the time of admission.

Examination of the blood showed a slight secondary anemia in both cases and a normal differential white cell count. The urine was normal and renal function in both seemed to be entirely normal. The Wassermann and Pirquet tuberculin tests were negative. There were no abnormal neurologic signs to explain the marked trophic disturbances.

Both children were unusually alert, above the average in intelligence for their age, exceedingly active except for their inability to walk and amusing on account of their ceaseless intelligent chatter.

The skin over the entire body was moist, exceedingly delicate and transparent.

In the older child the characteristic cutaneous lesions were observed on the scalp, on the lobes of both ears about the inner canthus of both eyes, on the lower part of the nose and at the corners of the mouth. There were no lesions on the trunk. Well circumscribed, red papular scaly lesions covered the region of both olecranon and the dorsal surfaces of both hands involving all the finger-nails in the form of a paronychia. Similar lesions were distributed about the knees and the dorsal surfaces of the feet, involving all the toe nails.

The lesions in the younger child had a somewhat similar distribution about the face, especially the mouth, eyes and ears, and the extremities except that the finger nails and toe nails were not so extensively involved. The younger child had lesions about the rectum and over the sacrum. She had much more looseness of stool than the older child. Organisms were recovered from all the cutaneous lesions in both cases, were demonstrable in stool cultures and were readily grown from blood cultures.

Both patients were extremely resistant to treatment, which consisted of local applications to the cutaneous lesions, the use of ultraviolet radiation, neoarsphenamine, vaccine prepared from the cultures, occasional blood transfusions and dietary management. Dilute solutions of copper sulphate seemed to be most effective for the cutaneous lesions but nothing really produced any lasting improvement. The physical state of both children progressively declined. They were taken from the hospital

after a stay of four months, entirely unimproved, and died a few months later from marasmus and terminal pulmonary infection.

CASE 4 (C B)—A girl, aged 8 years, reared on a farm in North Dakota, was brought to the University Hospital in November 1928 with the complaint of chronic eruption of the skin. The lesions first appeared when she was 10 months old about the corners of the mouth and the nose, extending later to the extremities. They were pustular and showed a tendency to dry scaling and thick crusting. They periodically healed only to reappear again in aggravated form. The condition had continued all through the child's life since infancy.

A complete loss of hair of the scalp, eyebrows and eyelashes had occurred four different times since the beginning of the eruption and seemed to coincide with the height of the eruption and its reappearance with subsidence and partial healing of the lesions.

Looseness of the bowels and chronic bronchitis were a continually recurring complaint.

There was no history of tuberculosis or other chronic disease or cutaneous disorder in the family. One brother was living and well.

Birth was normal. The child was breast fed for one year and gained well up to the time the eruption appeared. After that she was continually underweight although the increase in height has been adequate. Anorexia had been a persistent complaint.

At admission the child presented a thin, pale appearance. The stature was adequate for a child of 8 years. Slowness of speech and listlessness were marked but the mental faculties seemed unimpaired. There were numerous bald patches on the scalp and the remaining hairs were short, thin and very dry. The eyebrows and eyelashes were intact. The teeth showed a great deal of decay but the mouth and throat showed no signs of disease.

Except for the marked malnutrition, apparent anemia and cutaneous lesions, the physical examination was normal. The blood picture was that of a mild secondary anemia. The tuberculin and Wassermann tests were negative.

The cutaneous lesions consisted of dry, scaly, papulopustular patches, tending to fairly thick crusting with a red slightly indurated and inflammatory base. These lesions were located about the lips and the corners of the mouth and on all the extremities. The dorsal surfaces of both hands and feet, all the nails of both hands and several toe-nails on both feet were extensively involved. Large, apparently coal-scoring lesions were present on both forearms about the knees and on the lower part of the legs but the trunk, genitalia and rectum showed no involvement.

Scrapings from all the cutaneous lesions and cultures from the throat and the stool showed the organism of thrush—*Oidium albicans*—present in massive growth. The organism was not found in expectorated material and in blood culture.

The characteristic resistance of this disorder to all forms of treatment when it extensively involves the organism and becomes a systemic infection was exhibited in this case also.

Of the local medications, silver nitrate and dilute solutions of copper sulphate seemed to be the most effective. Improvement was noted also after ultraviolet irradiation coupled with dietetic and hygienic management. Arsenicals, iodides, and vaccine prepared from culture material seemed to be entirely without effect.

The characteristic remissions and exacerbations continued to occur in spite of any form of treatment. The child was discharged practically unimproved after a stay of over four months in the hospital.

Nothing was heard from the patient until a recent inquiry for her was made. Her mother wrote as follows:

Her sores bothered her constantly the winter she came back from the hospital in Minneapolis, but toward spring she started to improve. That summer (1929) she felt fairly well and her skin was clear most of the time. In the late fall and early winter of the same year the sores broke out again and she missed three months of school.

Since then her condition has not been bad, she has attended school quite regularly up till this last winter when she became worse. In addition to the old trouble she contracted measles

and that certainly set her back. She lost all her hair and the eruptions, especially around her ankles, have been worse than ever—pus and blood trickle out continually. Sometimes the sores itch so that she cannot sleep at night, and lately her eyes have been so sore. These last days she has felt somewhat better. She has grown considerably since you saw her, and whenever the sores heal up, she runs around and plays and is about as spry as any youngster."

The interesting feature of the cases reported consists in the extraordinary symptoms presented. The dwarfing effect of the disease presented in two of the cases and the generalized alopecia noted in three of them have to my knowledge not been reported in the literature. The fairly rapid form of sepsis observed in the case of the infant also seems to be exceedingly rare.

All four of the cases illustrate the formidable nature of this disorder when it becomes a generalized infection, and the remarkable ineffectiveness of any form of treatment.

920 East Fifty-Ninth Street

ABSTRACT OF DISCUSSION

DR. ISAAC A. AET, Chicago. Thrush infection is common in the new-born period; it is rare in older children and certainly uncommon in adults. It is assumed that thrush infection does not occur in the mouth cavity unless there has been some injury to the oral mucous membrane or the resistance of the infant has been lowered by nutritional disturbances. Professor Czerny said that in his experience thrush infection did not occur in a normal infant. I recall, however, periods in the nursery for the new-born when thrush infection occurred among the babies probably as the result of some temporary failure in the aseptic technic. There is no doubt that the fungous infection may spread to the pharynx and may descend through the larynx into the bronchial tubes or through the esophagus into the stomach and intestine. It has also been recorded that these thrush organisms may gain access to the blood stream, but again it must be assumed that in such cases the patient's resistance is low or that he is in a cachectic state. It seems to me that there is no reason why a generalized thrush infection should not occur. Thrush in older infants and children is most often associated with diarrheal diseases, perhaps the part played by a systemic thrush infection in the severity of the illness has been generally overlooked and the cause of the severe symptoms and the death has been assigned to alimentary infections.

DR. FREDERICK W. SCHLUTZ, Chicago. It is true that thrush infection is exceedingly common in the infants who are not doing well but this type of picture as represented by the four cases just reported is, I believe, exceedingly rare. It seems that this ordinarily fairly harmless agent can, under the right sort of conditions, produce pathologic conditions which so seriously affect the child in a trophic way that it eventually dies. I think the baldness in three of these cases (in two of them it showed permanently and will doubtless become so in the third) is unique. The fact that the last child has been more or less under treatment for a period of something like seven or eight years indicates the peculiar trophic systemic effect this disease can have. Any treatment tried so far has been ineffective. I should like to try some of the dyes by the intravenous route and possibly roentgen therapy. At the time these cases were under my care, treatment along these lines was not quite as advanced as it is at present. I have, of course, no assurance that such treatment would be effectual. It seems that in the end all these patients finally succumb to the disorder. I think it is probably true that the condition is apt to be overlooked in children and especially in older children. One expects to see thrush in the infant not doing well. It may involve the entire gastro-intestinal tract and the internal organs and in that way contribute to the fatal termination of the case. The picture itself is rare and I have not been able to find a reference in the literature to the peculiar effects the disease may produce, such as complete dwarfing and complete and permanent loss of all hairs of the scalp and face.

ACACIA IN THE TREATMENT
OF NEPHROSIS

MARK W DICK, MD

EDNA WARWEG, MA

AND

MARIE ANDERSCH, PHD

IOWA CITY

The use of acacia intravenously in the treatment of edema due to nephrosis has been advocated¹. The rationale of this treatment is based on the fact that acacia is an inert colloid which, when introduced into the blood stream, will raise the osmotic pressure of the blood above the levels at which edema occurs. The theory is logical, but our experiences with its use have been disappointing.

Acacia in amounts approximating 1 Gm per kilogram of ideal body weight has been given intravenously to four children with nephrosis in order to combat edema. The first administration of acacia was markedly effective, but not only were succeeding injections progressively less effective in reducing edema but other unfavorable symptoms developed. In each child the liver became markedly enlarged and tender, and simultaneously with a period of acacia treatment the serum protein, particularly the albumin fraction, dropped to dangerously low limits, remaining very low as long as the use of acacia was continued, and increasing very slowly after the use of acacia was stopped. The individual reports follow.

REPORT OF CASES

CASE 1—J A J, a girl, aged 3 years, was brought to the hospital Aug 30, 1932 because of swelling of the ankles, hands and feet, and sore throat. The patient had been well until five weeks previously. At the beginning of her illness she had a series of "boils" in the left axilla, which were opened and drained, during which time she contracted a "cold" and several times complained of a sore throat. Swelling of the face, feet and ankles soon became noticeable and was associated with scanty urine. The temperature was only slightly elevated.

When first examined at the hospital she had slight generalized edema, pallor of the skin, subacutely inflamed tonsils and pharynx, and a blood pressure of 105 systolic 70 diastolic. The urine contained rather large quantities of albumin, numerous casts and white blood cells but no red blood cells. The hemoglobin was 80 per cent, red blood cells 5,400,000, white blood cells 11,200, with a normal differential count. The blood Wassermann reaction was negative. The serum protein was 3.5 per cent, nonprotein nitrogen 34.6 mg per hundred cubic centimeters, and the cholesterol 296 mg per hundred cubic centimeters. The throat was treated conservatively. A high protein diet was given. After a few days in the hospital the edema rapidly increased.

Thyroid was administered with indifferent results. Acacia was given at irregular intervals intravenously as indicated in chart 1, approximately 1 Gm being used per kilogram of body weight. Ampules of 30 per cent acacia and 4.5 per cent sodium chloride were used, diluted with equal volumes of distilled water. Some reduction in edema was noted after acacia therapy, with symptomatic improvement. The patient left the hospital for a period of three weeks returning with marked generalized edema, fever and an infection of the upper respiratory tract. The urine still contained large amounts of albumin and numerous casts, but no blood. The total serum protein was 3.1 per cent, with the albumin fraction 1.1 per cent and the globulin 2.0 per cent. Acacia, salyrgan and ammonium chloride were given, in an effort to combat the increasing edema.

In spite of generous dosages of acacia the edema was always present, varying from day to day. The infection of the upper respiratory tract progressed to bilateral otitis media, the edema subsequently increased rapidly, and December 24 the patient died. A total of 285 Gm of acacia was given intravenously. Necropsy was not permitted. Chart 1 shows the total protein values of the blood together with the amounts of acacia and the times it was given during the course of the disease.

CASE 2—D J, a girl, aged 2 years, was brought to the hospital, Sept 8, 1934, because of swelling of the face, abdomen, arms and legs. Three days previously, swelling of the eyelids had been noticed.

Examination showed marked generalized edema, slight injection of the tonsils and pharynx, and mild paranasal sinusitis. The urine contained rather large quantities of albumin and many casts, but no blood. The hemoglobin was 70 per cent, red blood cells 4,800,000, white blood cells 15,000, with a normal differential count. The blood Wassermann reaction was negative. The serum protein was 3.96 per cent, with the albumin fraction 1.19 per cent and globulin 2.77 per cent. The nonprotein nitrogen was 28.6 mg per hundred cubic centimeters and the cholesterol 667 mg.

A high protein diet was given and the infection of the upper respiratory tract was treated conservatively. Acacia was given intravenously in dosages of 1 Gm per kilogram of theoretical body weight at irregular intervals, as shown in chart 1, ampules of 30 per cent acacia and 4.5 per cent sodium chloride diluted with equal volumes of distilled water being used. Marked reduction in edema was noted. During acacia therapy the serum total protein fell rapidly from 4 per cent to 1.9 per cent.

The liver became enlarged four finger-breadths below the costal margin and was very tender. Several transfusions were given to combat an increasing anemia. On October 11 there was a sudden increase in edema with hydrothorax, death came quickly and without fever as a result of embarrassment of respiration. The patient received a total of 129 Gm of acacia intravenously.

Chart 1—Amounts of acacia given intravenously to patients J A J and D J and the serum proteins.

At necropsy there was generalized edema of all the subcutaneous and internal connective tissues with ascites and bilateral hydrothorax. The liver was enlarged to twice its normal size and was grossly yellow.

Microscopic examination showed the increased size to be due to an engorgement of the liver cells with vacuoles thought to contain acacia. The kidneys were large, swollen and pale yellow. The essential lesion proved to be a deposition of fat in the convoluted tubules, there being very little evidence of glomerular damage. However a few crescents were seen as well as a small amount of blood within the tubules. The lungs were boggy and heavy and showed congestion and edema. There was marked enlargement of the mesenteric lymph nodes, and the malpighian corpuscles of the spleen were very prominent. There was microscopic evidence of acacia in the liver, spleen, kidneys, lungs, lymph nodes and bone marrow. Analysis of the liver and transudate fluids showed the presence of acacia in appreciable amounts. The acacia values were determined by hydrolysis of protein-free filtrates and the determination of the resulting pentose.² The heart blood plasma contained 21 per cent acacia, the pericardial fluid 0.6 per cent, the peritoneal fluid 11 per cent, the bile 2 per cent. Analysis of the liver showed 39 per cent acacia.

CASE 3—D S, a boy, aged 6 years, came under observation June 11 1932, because of swelling of the entire body. The

onset occurred four months previously with influenza and an infection of the upper respiratory tract. Edema appeared in the face and ankles two weeks later, rapidly spreading to the remainder of the body and becoming progressively worse.

Examination showed generalized edema subacute faucial and pharyngeal tonsillitis, mild sinusitis and pallor. The blood pressure was 96 systolic 60 diastolic. The urine showed a rather large quantity of albumin and casts, but no blood. The hemoglobin was 70 per cent, red blood cells 2,450,000 white blood cells 6,150 with a normal differential count. The blood

Chart 2—Amounts of acacia given intravenously to patients D S and R O together with total serum protein and serum albumin

Wassermann reaction was negative. The serum protein was 47 per cent. The nonprotein nitrogen was 53 mg per hundred cubic centimeters and the cholesterol 320 mg.

A high protein diet was prescribed. The infection of the upper respiratory tract was treated conservatively. Blood transfusions were given frequently. Edema increased and acacia was given intravenously, approximately 1 Gm per kilogram of body weight in concentrations varying from 6 per cent to 15 per cent. Ampules of 30 per cent acacia with 45 per cent sodium chloride diluted with distilled water were used. The edema varied at first decreasing after acacia but later very little effect was noted after repeated generous dosages of acacia. Thyroid and salyrgan had little effect. During a period of six months of acacia therapy the liver enlarged almost to the umbilicus and was very tender. Also during this period of acacia administration the serum protein fell to 15 per cent. Because of the enlarged liver acacia therapy was discontinued after a total of 705 Gm had been given intravenously. With repeated blood transfusions and treatment of the infection of the upper respiratory tract gradual improvement was noted.

Dec 12 1934, two and a half years later the patient was edema free and had no symptoms. The liver was still enlarged three fingerbreadths below the costal margin. The serum protein was 534 per cent but the albumin fraction was only 175 per cent and the globulin 358 per cent. The urine still contained a trace of albumin but no casts or red blood cells. The values for the serum proteins together with the amounts and time of acacia therapy are shown in chart 2.

CASE 4—R O a boy aged 10 years was brought to the hospital Aug 30 1934 because of swelling of the entire body, decreased urine output weakness and difficult breathing. The onset had occurred seven weeks previously with puffiness of the eyelids which was followed by gradually increasing generalized edema. Albumin had been found in the urine three weeks before he came to the hospital.

Examination showed generalized edema with marked ascites, pale skin, chronic faucial and pharyngeal tonsillitis and chronic paranasal sinusitis. The blood pressure was 115 systolic 65 diastolic. The urine showed a large amount of albumin and occasional casts but no blood. The hemoglobin was 80 per cent, red blood cells 3,980,000 white blood cells 7,500, with a normal differential count. The blood Wassermann reaction was negative. The blood analysis showed a serum protein of 385 per cent, a nonprotein nitrogen of 357 mg per hundred cubic centimeters, and a cholesterol of 728 mg.

A high protein diet was prescribed. The infection of the upper respiratory tract was treated conservatively. Acacia was

given intravenously in dosages of approximately 1 Gm per kilogram of ideal body weight. Ampules of 30 per cent acacia with 45 per cent sodium chloride were used, diluted with an equal volume of distilled water. Reduction in edema was at first noted with acacia therapy. However with repeated dosages the effect became less until little reduction in edema was observed. Thyroid and ammonium chloride were given in generous dosages without noticeable results. Repeated transfusions were found necessary to combat an increasing anemia.

During acacia administration the serum proteins fell to a low level of 1.68 per cent, rising to 2.56 per cent after acacia was temporarily discontinued and falling again to 1.12 per cent during a second course of acacia administration, as shown in chart 2. At this time the patient's liver enlarged to three fingerbreadths below the costal margin and became very tender. Marked ascites made breathing difficult, and abdominal paracentesis was necessary on several occasions. The first abdominal paracentesis was made twenty-four hours after the giving of 30 Gm of acacia intravenously. The ascitic fluid contained 0.3 per cent acacia and the blood plasma 21 per cent.

Acacia administration was discontinued after a total of 492 Gm had been given and a subsequent rise in serum proteins was noted with a value of 3.27 per cent December 17. The urine had continuously contained from 2 to 9 Gm of albumin per liter by the Esbach method. Chart 2 shows the values for the serum proteins together with the amounts of acacia and the time it was given.

The patient is symptomatically improving with conservative treatment of the infection of the upper respiratory tract, high protein diet, blood transfusions and occasional abdominal paracentesis. The liver remains enlarged but slightly less so than during administration of acacia.

Deposition of acacia in organs of experimental animals, especially in the liver with resulting hepatic damage, has been reported^{2a}. Thus, together with its presence in edema fluid is sufficient to give rise to hesitation as to its continued use. Acacia fixed in tissue and having found its way to deposits of edema fluid is definitely defeating the purpose for which it was given. The decrease in serum protein, however, was the most alarming feature. If this was a result of the administration of acacia, the lowering of osmotic

Chart 3—Amounts of acacia given intravenously to dogs 1, 2 and 5 together with total serum protein, serum albumin and serum globulin

pressure, caused by the loss of serum protein, more than nullified the effect of the acacia. It was not wholly clear, however, whether the decrease in serum protein observed in these children was caused by, or merely accompanied, the administration of acacia. To aid in answering this question four normal dogs were given acacia intravenously in dosages of 1 Gm per kilogram

of body weight, and a control dog was given Ringer's solution intravenously in corresponding volumes. Daily serum protein partition, blood acacia, hemoglobin and cell volume determinations were made. The serum protein determinations were made by the micro-Kjeldahl method.³ The acacia values were determined by hydrolysis of protein-free filtrates and the determination of the resulting pentose,² hemoglobin was determined by the method of Newcomer, and cell volume values were obtained with a Van Allen hematocrit. The data obtained are shown in charts 3 and 4.

EXPERIMENTS ON DOGS

Dog 1 was given acacia daily, 1 Gm per kilogram of body weight for seven days. The blood acacia reached a maximum on the fourth day and thereafter decreased rapidly, notwithstanding continued administration. The serum proteins, however, continued to decrease, the albumin fraction showing a continuous lowering, the globulin fraction being more variable but showing some decrease. The lowest total protein value was reached on the ninth day, a decrease of 52 per cent, the blood acacia at this time being very little higher than the value observed after one day's administration. The day after the

third day of administration, and acacia disappeared from the blood rapidly during the recovery period. The serum albumin decreased from 31 per cent to 168 per cent with three days of acacia administration, then rose again to 27 per cent even though acacia was being given daily. The recovery of the albumin level was slow, the value reaching approximately its initial level on the fifteenth day. The serum globulin fell more slowly at first, then more rapidly as the albumin values tended to become constant. The rise during recovery was also more rapid. With the second acacia period both albumin and globulin decreased rapidly and steadily, the globulin decreasing to 104 per cent in five days, the albumin to 195 per cent. A total protein decrease of 47 per cent was noted.

Dog 4 was allowed a smaller rest period between the two acacia periods. The blood acacia values in this dog were not high, but acacia remained in the blood at a more constant level after administration was discontinued. The highest acacia values were observed at the end of the second period of administration. In dog 4, practically the entire decrease of serum protein during the first period of acacia administration was due to decrease in albumin. During the five-day recovery period the albumin tended to rise, but the globulin fraction fluctuated irregularly. During the second five-day acacia period the albumin remained at 2 per cent, the globulin remained constant at 21 per cent for three days and then dropped rapidly to 1 per cent. Thus the fall of serum protein during the second acacia period was due almost entirely to decrease of globulin. There was a decrease of total protein of 52 per cent. When acacia administration was discontinued, both fractions of serum protein increased slowly.

COMMENT

It will be observed that the level of acacia in the blood of the four dogs varied considerably, even though all the dogs received 1 Gm of acacia per kilogram of body weight daily for at least five days. Likewise, the apparent period of recovery varied, being least in dog 4 during the five-day interim between periods and most rapid, probably, in dog 3, whose total protein reached its original value on the fifth day, although the albumin did not reach its original value until the tenth day.

All dogs, including the control dog, showed a fairly uniform fall in hemoglobin and cell volume while receiving intravenous fluid and having blood samples drawn (about 6 or 7 cc of whole blood daily). The fact that the hemoglobin and cell volume of the dog receiving Ringer's solution fell proportionately to those receiving acacia would discredit a dilution phenomenon due to acacia. The decrease in protein cannot be ascribed to added fluid due to acacia, for the sharpest drop often occurred before the acacia level had reached its maximum. In dog 1 the level of blood acacia actually fell from 21 per cent to 0.9 per cent in four days, while acacia was being given daily, the lowest serum protein value for this period occurring when the serum acacia was lowest. In dog 2 serum albumin decreased to 2.9 per cent while the acacia increased to 27 per cent, but a further increase of acacia to 3.6 per cent was accompanied by an increase in the serum albumin level. The total protein of dog 4 fell from 6.15 per cent to 3.02 per cent in fourteen days, while the level of serum acacia remained approximately constant, varying only between the levels of 1.2 per cent and 2 per cent. There would seem to be no accurate correlation between the fall in serum protein and the rise in serum acacia. All the dogs showed a distinct tendency to maintain the serum albumin level at or above 2 per cent. A decrease below this level was invariably followed by a rise, even though, as in dog 2, the increase could not be maintained. This is quite different from the serum albumin of the four nephrotic

Chart 4—Amounts of acacia given intravenously to dogs 3 and 4 together with total serum protein, serum albumin and serum globulin.

administration of acacia was stopped both fractions of the serum protein showed a definite increase. Unfortunately this dog disappeared, and the blood could not be studied during the remainder of the recovery period.

Dog 2 was given acacia daily for seventeen days. The amount of acacia in the blood stream was higher after one administration than the highest value observed in dog 1. The blood acacia value fluctuated more or less but reached a maximum of 3.6 per cent on the fourteenth day of administration. After this, the acacia level fell for three days, rising again to 3.2 per cent on the last day of administration. With this dog the decrease in serum albumin was prompt and marked. The serum globulin decreased more slowly and reached its minimum later. After the albumin level had fallen to 0.95 per cent, a transient rise occurred, which was maintained for several days. During the remainder of the acacia period the albumin values tended to fluctuate between 1.0 and 1.6 per cent. The globulin values showed some fluctuation but seemed to be still decreasing at the time acacia was discontinued. A maximum decrease in total protein of 61 per cent was noted. During the recovery period both the albumin and the globulin fractions increased steadily but were not yet normal when the experiment was discontinued.

Dogs 3 and 4 were given acacia for periods of five days then a rest period, followed by a second period of acacia administration. Dog 3 showed a maximum blood acacia value on the

THYMIC DEATH—WALDBOTT

GEORGE L. WALDBOTT, M.D.
DETROIT

657

children, which decreased to values below 1 per cent. None of the dogs exhibited an albuminuria, whereas all the children were losing albumin steadily through excretion in the urine. The protein of the control dog rose slowly during the experiment, probably because of the high protein diet the dogs were fed. When the osmotic pressures of the lost serum protein and of serum acacia were calculated, it was noted that the values were not equal. In dog 1 there was a drop of 284 per cent of total protein in six days, which by Govaert's formula should exert an osmotic pressure of 10.95 cm of water. During the same period the serum acacia rose only 0.4 per cent, which according to Dodds and Haines⁴ should exert an osmotic pressure of only 0.8 cm of water. The fall in serum protein does not appear to be due to an effort on the part of the body to preserve a constant serum osmotic pressure by lowering serum proteins by an amount sufficient to offset an equivalent osmotic pressure due to acacia. It would seem that serum acacia does not merely displace serum protein.

SUMMARY

The use of acacia intravenously to combat the edema of nephrosis was found to have only a transient or slight effect on the edema. Continued use of acacia led to a marked lowering of the serum protein and to the development of an enlarged tender liver. When the acacia therapy was discontinued serum protein tended to remain low, the liver slowly resumed its normal size. In two patients acacia was found in deposits of edema fluid, and in one of these coming to necropsy, appreciable amounts of acacia were found by chemical analysis in the liver, with evidence by microscopic examination of deposits in the bone marrow, lymph nodes, lungs, kidneys, spleen and liver. In dogs the administration of acacia intravenously in dosages equivalent to those used in patients with nephrosis produced a marked lowering of the total serum protein affecting both the albumin and globulin fractions. This reduction in protein did not appear to be a simple dilution effect. The exact mechanism of protein reduction remains unknown. However, the degree of reduction of serum protein was not related to the amount of acacia in the blood stream. The level of serum acacia varied markedly even with daily injections and could not be constantly maintained. When the daily administration of acacia was discontinued, the serum protein values of the dogs returned to normal much more rapidly than was observed with the nephrotic children.

The use of acacia intravenously in patients with nephrosis was not found of value and was associated with undesirable results.

In the lymphoid structures in cases of so-called thymic death Symmers¹ described areas which he held to be indicative of anaphylactic changes. Hammar² suggested repeatedly a state of unusual sensitivity as an underlying factor in so-called thymic death. Yet the anaphylactic conception of "thymic death" has not gained adherents very rapidly. Thus, I believe, is due to three facts. 1. Until recently, anaphylactic shock has been held to be a phenomenon occurring only in animals—not in man. 2. It was not believed to be produced by ways other than injection. 3. It was thought to be always associated with antigens of protein nature and even mechanical stimuli were involved in the production of thymic death seemed to weigh heavily against this theory.

Yet there are various observations that suggest an association of the thymic death problem with allergy. For many years past the medical literature has linked with the so-called thymic diathesis features that are now considered allergic, such as the tendency to nasal and bronchial catarrhs, to enlarged tonsils, adenoids and other lymphoid structures, to eczema, and to eosinophilia. Of particular significance in this respect is frequently a familial tendency to "thymic death," as attested by reports in the literature.³ In children with a roentgenologically enlarged thymus true allergic manifestations often develop in later life.⁴ In allergic families I have observed on several occasions sudden death which presented the clinical and pathologic characteristics of so-called thymic death. In recent autopsies on asthmatic patients, descriptions of enlargement of the thymus and other lymphoid tissue and a decrease of medullary substance of the adrenals have played an increasing role.⁵ The same has been noted in cases of sudden death due to an overdose of serum and pollen.⁶

HUMAN ALLERGIC SHOCK

Since there has been very little known concerning human allergic shock, it is necessary to present a few observations concerning this phenomenon. In men, allergic shock can probably best be studied in work with pollen extracts, for one is here dealing, as a rule, with a known degree of sensitivity, with a known antigen, namely, the pollen, and with a known dose. It was determined that the production of allergic shock depends primarily on three factors: first, on the degree

Potential Capability of the Brain—The most wonderful feature of the human brain is its extraordinary potential capability. An obvious instance is seen in the spread of education of the reading and writing mechanism and the classes and the masses and varying degrees among both the acquisition of knowledge and to its application to the arts and the crafts. The important, and also individually varying factor is the grade of mind or general intelligence which may vary from that of the imbecile or general defective up to that of the genius and whose psychomotor possibilities, according to its grade, are limited solely by opportunity and environment.—Bolton J S. *The Evolution of Mind*, *Lancet* 1 728 (March 30) 1935.

⁷ The differentiation between anaphylactic and allergic shock, if justified at all is of little importance to the clinician and is therefore not applied in this paper (Waldbott G L. *The Types of Human Hypersensitiveness* *J A M A* 102 1631 [May 12] 1934)

of individual sensitivity—whether inherited, as for instance in cases of atopic asthma, or acquired, as in individuals who are sensitized by previous injections of horse serum, second, on the size of the overdose of the injected antigenic substance, third, on the rapidity of its absorption. As to the latter point, it was found that in sudden deaths following the administration of serum the accidental injection into a vein was responsible in the majority of cases^{8b}.

The manifestations of allergic shock are subject to great variations. There is usually a predominance of respiratory and dermal symptoms. These are due either to true allergic edema of the urticarial type or to edematous hemorrhagic lesions, which are followed by necrosis. As Kline and Young⁹ pointed out, the latter type of lesion may be considered as evidence of local anaphylaxis (Arthus phenomenon) and is apt to arise in

Shock due to contact of the lip with a minute particle of egg. Epinephrine effected prompt relief. (Courtesy of W. W. Duke, Kansas City, Mo.)

any part of the body. Outside of dermal edema and respiratory symptoms, these pathologic changes give rise to such additional manifestations as convulsions, hematuria and severe gastro-intestinal pains. It has been stated by Roth and Szauder⁹ that the organs first reached by the antigen are those which are principally involved. Hence pulmonary and hepatic symptoms are more frequent, since the antigen is largely absorbed through the venous circulation and the first capillary systems that it reaches are those of the lungs and liver. If a previous allergic or nonallergic focus such as eczema, a tooth abscess or a sinus infection has been present, symptoms attributable to a flare up of this focus may arise¹⁰. The mode of introduction of the antigen into the body may also alter the symptomatology of shock. If it is given as an intravenous injection, collapse and death may occur so rapidly that no symptoms referable to a single organ can be noticed¹¹. Two features are usually not sufficiently stressed, namely, that nonprotein substances may produce the same symptom complex as pollen or serum and that shock can be produced by ways other than injection. The latter fact is best illustrated by the accompanying illustration, which I owe to the courtesy of Dr. W. W. Duke of Kansas City, Mo. This presents a case of shock brought on by dermal absorption through contact of an (excoriated?) area of the lip with an exceedingly small amount of egg. In this case it was particularly noteworthy that an area of local edema was present at the site of contact (the raw area on the lip) similar to a local wheal that follows an injection of pollen and serum.

I have recently collected¹² records of thirty cases of allergic shock in which absorption of the antigen took place by routes other than injection. The following modes of absorption were held responsible in thirteen cases, ingestion of food, in five the taking of drugs by mouth, in five, inhalation, in two, contact of the antigen with the skin, in three, cold and in two heat. Among the foods, egg was the most common source, among the drugs, acetylsalicylic acid.

OBSERVATIONS IN "THYMIC DEATH"

With these facts in mind, I reviewed a series of 104 autopsies from various hospitals in which the diagnosis of thymic death had been made¹³. Sixty of these cases were excluded because there were sufficient other indications to account for death. The remaining thirty-four were divided into three groups: those in which no cause whatever for death could be determined, those in which minor, usually nonfatal, conditions were coincident with death, and those in which the so-called thymic syndrome had developed, i. e., stridor, dyspnea and shock, followed by bronchopneumonia. In all these cases there were uniform changes in the lungs, namely, edematous hemorrhagic areas into the alveoli. According to the advancement of these lesions a more or less severe degree of necrosis was present. Traumatic emphysema alternating with atelectasis was noted, and occasionally eosinophil cells were present. In some cases there was what seemed to be a secondary enlargement of the right heart. In some, hypoplasia of the adrenals, particularly of the medullary portion, was noted.

INTERPRETATION

In interpreting these changes it seemed at first that I was dealing with an urticaria-like allergic phenomenon. However, the relative absence of eosinophils and the more or less marked degree of necrosis present was not compatible with this explanation. From true bronchial asthma, on the other hand, these lesions are so strikingly different that they do not admit a comparison. In reviewing the available literature on the pathology of anaphylactic shock in man, edematous lesions associated with necrotic areas in the lungs as well as in other tissues, particularly in the liver, are described as the most characteristic changes. This is particularly emphasized in the thorough description by Dean¹⁴ of

a case of death following the administration of tetanus antitoxin. These lesions correspond accurately with those in the present series.

If these data are interpreted as indicative of anaphylactic shock, the question arises whether or not enlargement of the thymus gland could be considered an allergic phenomenon. Such an assumption would not be in accordance with clinical observation, for routine x-ray films of patients with hay fever and asthma do not manifest an enlarged thymus gland. Skin testing on children with roentgen evidence of an enlarged thymus does not, as a rule, reveal positive reactions at the time when clinical evidence of an enlarged thymus gland is present. Yet, in later years, as Anthony and I¹⁵ pointed out, true allergic symptoms do develop in these patients with positive skin reactions in an unusually large percentage of cases. This therefore suggests the possibility that enlargement of the thymus gland may constitute a preallergic phenomenon.

In order to shed further light on this problem I attempted to study the pathologic changes of asthma in its earliest development. I obtained autopsies on two infants in which true allergic asthma had been present for as short a time as three weeks and six weeks respectively.¹⁵ Again, in these cases a striking resemblance to the changes of "thymic death" as well as of anaphylactic shock was found at autopsy. There are considerably less emphysema, little evidence of bronchospasm and a lesser degree of secretion of the mucous glands in early infantile asthma than in cases of long standing. This might be accounted for by the fact that the organism has not yet had sufficient time to develop such anatomic changes as a compensatory thickening of bronchial musculature, enlargement of mucous glands, eosinophilia and leukocytosis, in other words, lesions which in all probability represent evidence of an adjustment of the body to the functional disturbance present. On the other hand edematous areas of the alveoli, necrosis and lymphocytic infiltration quite similar to what is found in acute anaphylactic lungs¹⁴ are decidedly more predominant features. It then appears likely that "thymic death" represents a preallergic phenomenon that is probably identical with anaphylactic shock. During this preallergic state the system does not appear to be endowed with a sufficient defensive mechanism against the invading antigen. When this antigen is ingested, inhaled, injected, absorbed through the skin or possibly formed in the system as the result of mechanical or thermic stimuli the patient succumbs suddenly instead of developing an asthmatic attack.

As an illustration of this theory I will give a brief report of the following instance, which I had occasion to observe.

F. M., a girl, aged 2 years with a strong family history of allergy, developed typical stridor, dyspnea, cyanosis and shock followed by a low grade bronchopneumonia at the height of the ragweed season in 1933. Although the skin reactions for ragweed were negative, an attempt to desensitize the patient for ragweed during the following winter was made. This had to be abandoned because attacks similar to the first one followed each injection of the extract. At the beginning of the 1934 ragweed season a nasal catarrh developed progressing rapidly to extreme shock and the child died within two days. At autopsy the thymus weighed 35 Gm.¹⁶ and the lungs showed edematous hemorrhagic lesions associated with beginning bronchopneumonia.

TREATMENT

With the present state of knowledge it is of course impossible to outline definitely measures of prevention and treatment. There is no remedy known at present that will counteract anaphylactic shock once it has developed.¹⁷ It is true that urticarial lesions can be controlled by epinephrine. However, the aforementioned irreversible lesions, particularly the necrotic changes, have been but little influenced by this medicament in my experience. Concerning the administration of intravenous dextrose to counteract the edema, no definite data are at hand.

Of greater value may be the specific treatment, namely, the administration of extremely small doses of the sensitizing antigen in a manner similar to that in which allergic conditions are controlled at the height of their development. But this is possible only if one is familiar with the causative antigen and if death does not occur too rapidly. In most of the cases that I reviewed, death occurred instantly, in others, during the ensuing bronchopneumonia. Here such therapy may be in place, and it is perhaps the only specific treatment.

More valuable perhaps than treatment itself are measures of prevention. If one entertains seriously the allergic conception of thymic death, any child born to allergic parents could well be considered a potential candidate for it. This condition may or may not develop during its early childhood just as urticaria or hay fever may occur at any time of his life. All such measures as are proposed for prevention of asthmatic attacks should be considered. It is well to guard these children against exposure to weeds, flowers, face powder, sudden chilling, overheating, or the ingestion of foods or drugs to which they may be sensitive. Whether or not systematic skin testing will be successful in the recognition of the sensitizing agents is questionable. It seems that in this state skin sensitizing antibodies are not yet as prevalent as in cases presenting existing allergic manifestations. One may recall that, in some of the severe cases of fatal shock following injections of horse serum which I reviewed, previous skin tests were negative.

That a period of from two to three weeks between a previous absorption of an antigen and a subsequent one is instrumental in the production of shock in man as well as in animals has been brought out elsewhere.¹⁸ This should be borne in mind in connection with the ingestion of drugs, with previous anesthesia and with such foods that are not eaten frequently, or with inhalation of air-borne substances. Concerning hypodermic medication, an attempt should be made by history and by clinical observation to determine a possible sensitization to the material to be injected. Particular attention should be directed toward the prevention of accidental intravenous injections.

Roentgen treatment of the enlarged thymus did not prevent death in several instances.¹⁵ Many, however, believe that several small exposures of the thymus to x-rays produce a great deal of symptomatic relief, an effect which is comparable with that of small doses of x-rays over other lymphoid tissues, such as the spleen and the hilus glands in bronchial asthma.

SUMMARY

The evidence presented here suggests that the condition termed "thymic death" is a preallergic phenomenon similar to or identical with anaphylactic shock. This may be brought on by ingestion, inhalation, injection,

¹⁵ Waldbott G. L. The Pathologic Changes in Asthmatic Infants. *Am. J. Dis. Child.* 49: 1531 (June) 1935.

¹⁶ Repeated roentgen examinations failed to reveal evidence of thymic enlargement.

ABSTRACT OF DISCUSSION

DR B S KLINE, Cleveland While I subscribe to the belief that thymic death may be an allergic or para-allergic reaction, the observations in thirty-eight cases in which status lymphaticus was the principal or accessory cause of death at Mount Sinai Hospital in Cleveland in the past twelve years support the view of Symmers, presented in 1918, that the most impressive lesion in these cases is the degeneration and necrosis in the germ centers of lymph follicles throughout the body, particularly in the intestine, in the lymph nodes and in the spleen. While there are frequently primary changes in the heart, arteries, adrenals and thymus, and also secondary changes in the heart or in the vascular system and in the pulmonary system, these are not as impressive as the striking changes in the lymphoid tissues. I would class these pulmonary changes, the hemorrhages, edema and round cell infiltration (not eosinophilic as in ordinary clinical allergies) as secondary manifestations. Incidentally, there were patients particularly those dying soon after the onset of symptoms, who showed negligible pulmonary changes. Concerning the nature of the degeneration and necrosis in the lymphoid tissues, it reminds one of specific parenchymatous changes observed in several types of injury: arsenic and mercury poisoning, hormones in excess, and changes in the liver in eclampsia and in the pancreas in diabetes mellitus. The lesion is unassociated with vascular changes of inflammation. It also reminds one of changes in rheumatic endocarditis for instance, when there is no appreciable round cell infiltration but specific degeneration and necrosis of the endocardial cells. There are many views on thymic death and as many on the significance of status lymphaticus. I would say, having observed death in cases of slight burn or slight gastro-intestinal upset or slight operation done skilfully, that there does seem to be an underlying status lymphaticus that contributes to the death of the individual. The body in a case of thymic death has its lymphoid tissues damaged in one or more ways, possibly releasing some antigenic substance and following a subsequent release of the same or similar material or other material, changes occur that lead to secondary vascular and pulmonary changes and finally to death.

DR A GRAEME MITCHELL Cincinnati It seems to me that Dr Waldbott has argued intelligently for the fact that a certain number of cases of so called thymic death may be due to anaphylactic shock. I myself would prefer to accept this as quite possible but I do feel that the question is not settled. There are still a certain number of cases of so called thymic death in which obvious causes cannot be found but which may be linked up to some other type of disturbance of the thymus or lymphatic system. Dr Waldbott's discussion at least presents the idea that anaphylaxis must be carefully excluded as the cause of death in so-called thymic cases.

DR GEORGE L WALDBOTT Detroit Dr Kline suggested that the pulmonary changes may not be the cause of death in these cases. It is true that edema and necrosis may also be present in other organs. The following reasons however suggest that the pulmonary lesions are directly responsible for death. There are no changes as constant as those in the lungs, they are sufficiently extensive to interfere with respiration and death is usually of the asphyxiative type. There is a question as Dr Mitchell states whether or not allergy in the strict sense of the term is always responsible for the lesions in the lungs. In cases of toxemia of pregnancy, mercuric chloride poisoning and acute infections, Moon has described similar edematous and necrotic areas in the lungs which he explained on the basis of shock from liberation of histamine-like substances. This is also the explanation of many investigators of the origin of the allergic wheal. Between this type of shock and true allergic shock there may be a relationship similar to that which exists between the histamine wheal and the true allergic wheal.

A GRADED COURSE IN MEDICINE AS PART OF THE DENTAL CURRICULUM

LEON H COLLINS JR., MD

MARTIN P CRANE, MD

AND

BERNARD I COMROE, MD

PHILADELPHIA

To any one engaged in the practice of internal medicine or of dentistry today, it soon becomes apparent that in spite of the steady progress of both these professions there still remain uncultivated large areas in their mutual fields of clinical interest. This concept has been fully accepted for several years by leaders in medical and dental education in this and other countries. At the University of Pennsylvania the idea of incorporating into the dental curriculum a course in internal medicine was conceived by Dr Alfred Stengel, professor of medicine and vice president in charge of medical affairs of the university, and Dr Charles R. Turner, professor of prosthetic dentistry and dean of the school of dentistry. Such a teaching liaison has now been in operation for two years. It is our purpose in this communication to indicate to those engaged in medical and dental education the scope of these courses, the objectives that have been kept in mind, and the apparent results that have been obtained to date.

Our courses have been designed specifically to establish in the mind of the future practitioner of dentistry the idea that he should know at least the working vocabulary of the science and practice of internal medicine. Our aim is to transmit to the student of dentistry the idea of viewing a sick human being as much as possible after the manner of a competent internist. To date this has been our sole goal and therefore we have not attempted to teach methods of physical and laboratory examination as they are taught to students of medicine. In other words we have endeavored to illustrate the benefits that may follow the closer cooperation of the professions of dentistry and medicine.

The courses that we have conducted to achieve this goal are constituted as follows. Throughout the entire second year of the dental course there is given weekly one lecture that aims to introduce to the student the major concepts in the internal medicine of today. Through careful selection of subjects it has been possible to cover, during this year, a considerable amount of subject matter. During the year an idea of the progress of the course in the student's mind is gained by written quizzes in addition to the written examinations at the end of the first and second semesters.

Throughout the third year of the dental course, biweekly clinics are given. In these during the course of the year the attempt is made to amplify the accumulation of the basic facts of internal medicine begun in the second year. More important than this, however, is the attempt that is made to illustrate, as completely as possible to the student, the general clinical characteristics of the most frequently encountered medical disorders. We have attempted to cover as wide a field of internal medicine as seemed reasonable, aiming constantly to stimulate the imagination and curiosity of the student into those channels that may indicate to him respects in which such information may be of

From the School of Medicine and the School of Dentistry University of Pennsylvania

value in his practice of dentistry. In this course a written examination is given at the end of the first and second semesters.

Throughout the fourth year, groups of students, averaging about eight, meet in the presence of a member of the dental and of the medical faculties to discuss, at close hand, patients selected to illustrate the importance of correlating as fully as possible the best that these two professions have to offer. These classes meet once weekly and are arranged so that each student has eight such meetings during the year. These clinical conference groups are quite informal and are designed to promote pertinent discussion between the students and the teaching staff. At the end of the senior year a comprehensive oral examination in medicine is held.

Concerning the demonstrable results of these courses, it is obviously too early to speak. One result that does seem to be apparent is that the members of the dental and medical faculties of this university have come to cooperate more closely in their interchange of ideas in both clinical and investigative work. It is our belief that, if it has not succeeded in doing so already, this cooperative enterprise will show its fruits in the work of the graduates of the School of Dentistry. At the present time the subject matter presented in these courses, with the addition of data relating to internal medicine that may be of use to students and practitioners of dentistry, is being assembled in book form.

Clinical Notes, Suggestions and New Instruments

DESTRUCTION OF EPIPHYSES BY FREEZING

RUTH BLOUNT BENNETT M.D. AND W. P. BLOUNT M.D. MILWAUKEE

Disturbances of epiphyseal growth have been much studied from the clinical and experimental points of view in the past decade. Numerous proved and theoretical causes for osteochondrosis have been recorded. A careful search of the literature discloses only one case of stunted growth of the fingers as a result of freezing, however. Another instance (fig 1) is reported here.

Fig. 1—Appearance of hands in December 1932 showing the shortness of the digits and the fusiform swelling of the proximal interphalangeal joints of digits two, three and four.

A white girl, aged 8 years, seen in July 1932, complained of swelling of the proximal interphalangeal joints of the second, third and fourth fingers of the left hand. The patient had frozen all the fingers of the left hand, with the exception of the thumb, in December 1931 with subsequent loss of the fingernails. There was no disability until the swelling appeared in June 1932.

From the Milwaukee Children's Hospital

The developmental history was otherwise normal. With the exception of chickenpox in 1929 and scarlet fever in May 1932, the past medical history was negative. The Mantoux, Wassermann and microprecipitation (Kline modification) tests were negative.

When first seen there was swelling of the proximal interphalangeal joints of digits two, three and four, crepitation, and

Fig. 2—Roentgen appearance of both hands in December 1932 showing generalized atrophy on the left, the complete destruction of the epiphyses of distal phalanges two, three, four and five, and middle phalanges two, three and four.

some limitation of motion. The third and fourth digits were crooked with the apex of the angle medially and at the proximal interphalangeal joint.

The fingers were splinted temporarily, and the patient was seen for follow up in October and December 1932 and December 1934. Very little change occurred in the clinical appearance except for the greater variation in length. On the left, the corresponding fingers were shorter by the following amounts: index finger, 1 cm; middle finger, 1.3 cm; fourth finger, 1 cm; and fifth finger, 0.5 cm. There was slight habitual flexion deformity of the distal phalanges of the middle three digits.

Roentgen studies (fig 2) were taken of both hands in the postero-anterior direction. On the right the epiphyses are normal in distribution, regular in outline, and still open. On the left there is slight generalized bony atrophy. The epiphyses of the first digit, the other four metacarpals and the proximal phalanges are otherwise normal in appearance. The epiphysis at the proximal end of the fifth middle phalanx is also normal. Those of the distal phalanges of the second, third, fourth and fifth digits as well as the middle phalanges of the second, third and fourth digits are entirely absent. The metaphyses at these points are markedly irregular in contour and appear moth-eaten. The same irregular appearance is evident on the contiguous surfaces of the neighboring phalanges where there is no epiphysis. The proximal interphalangeal joints of the third and fourth digits are angulated with the apex laterally.

COMMENT

Osteochondrosis of the phalangeal epiphyses has been well known since 1909 when Thiemann¹ reported a case of multiple involvement of the fingers. Following his lead, eight men published reports of similar cases. Most of these reports are in roentgenologic journals and have not attracted the attention of the profession at large. In 1933 Ryffel² summarized the literature and added three cases from one family. The changes of Thiemann's disease are almost entirely limited to the proximal end of the middle phalanges. The cause is as obscure as that of the osteochondroses elsewhere.

In 1930 Löhner³ published the report of a case almost exactly similar to the one here reported, even to the onset six months

¹ Thiemann H. Juvenile Epiphysenstörungen. Fortschr. a. d. Geb. der Röntgenstrahlen 14:179, 1909.

² Ryffel H. Zur Thiemannschen Epiphysenerkrankung. Röntgenpraxis 5:423 (June) 1933.

³ Löhner W. Die Verschiedenheit der Auswirkung gleichartiger bekannter Schaden auf den Knochen jugendlicher und Erwachsener gezeigt an Epiphysenstörungen nach Erfrierung und bei Hamophilen Zen-trabl. f. Chir. 57:898 (April 12) 1930.

after freezing, the loss of finger-nails, and the involvement of the joints. He compared the roentgenograms to those taken of fingers following Volkmann's ischemia.

We also were interested in observing the similarity of this condition to epiphyseal destruction by freezing. A severe ischemia following supracondylar fracture resulted in an x-ray appearance almost the same as in this case except for the soft tissue contracture. The effect of prolonged ischemia, whether due to stopping of circulation by freezing or to mechanical obstruction, appears to be much the same as far as destruction of epiphyses is concerned.

COLD URTICARIA FOLLOWING MEASLES IN THREE SISTERS

J. L. KOBACKER, M.D. AND H. J. PARKHURST, M.D. TOLEDO, OHIO

In the investigations of cutaneous reactions and of peripheral vascular phenomena the wheal has been a subject of much interest. Its appearance under various influences has confused the investigators in their effort to fix a single ultimate substance or cause as the direct etiologic factor. Interest in urticaria due to cold has been fostered in part by its apparent pathogenic difference from those urticarial states which result from internal factors, allergic influences, histamine injections, burns and the like.

During recent years many cases of urticaria due to cold have been reported, especially in the German and Viennese clinics but the literature fails to reveal one instance of the occurrence of this condition following measles. Del Vivo¹ has reported a case in a woman aged 24, in which it appeared and persisted following scarlatina at the age of 16.

Its simultaneous occurrence in more than one member of a family must be extremely rare, since only one such instance could be found: cases in two children reported by Jadassohn and Schaaf.² Therefore we are reporting the following cases, which we have observed.

In June 1934 three sisters aged 8, 11 and 13 years, had measles. The course of the disease was typical rather mild and uneventful, and no medicine was administered. None of the children had ever received serum injections. Immediately following recovery, it was noticed that all three girls would develop hives in areas of the skin exposed to cold, as for example, following contact with a cold milk bottle. On one occasion the youngest child presented marked urticaria of the entire buttocks after accidentally sitting in a bucket of cold water. This phenomenon persisted throughout the summer and fall of 1934 and was brought to our attention by the mother who is a graduate nurse and a good observer.

When the sisters were examined by us in November and December 1934, the condition was still present but appeared to be subsiding. Cubes of ice were placed on the backs of the hands. After two and one-half minutes the areas thus exposed became red, and after five minutes of contact small wheals appeared which faded after five minutes. There was no dermographism. The oral mucosa was not and had not been affected by cold. The condition was the same in all three girls.

Physical examination revealed no other abnormality in these children. Laboratory data also were uninformative excepting eosinophilia (7, 10 and 13 per cent) in each case. The presence of eosinophilia must be considered as a quite usual accompaniment to the urticarial state. (Stool examinations failed to reveal evidence of any parasitic infestation.)

The fact that three sisters should begin to evince this abnormal skin reaction simultaneously and apparently as a result of their having passed through an attack of measles opens a field of speculation. However it seems most probable that the so-called H substance was elaborated or freed in greater amounts in the skin sensitized by the roseolar disorder.

The familial distribution of allergic tendencies requires no emphasis. The chief interest in these cases lies in the develop-

ment of an identical (allergic?) manifestation in all three simultaneously and probably as a result of the same factor.

Since we made these observations the urticarial tendency has continued to subside, and now (June 7, 1935) it has disappeared entirely.

THE USES AND ABUSES OF MODERN GLAND PRODUCTS IN GYNECOLOGIC DISORDERS

CLINICAL LECTURE AT ATLANTIC CITY SESSION

EMIL NOVAK, M.D.
BALTIMORE

If this paper dealt with gynecologic endocrinology instead of gynecologic organotherapy, it would be difficult to crowd within its restricted limits a recital of the brilliant accomplishments in that field, constituting as they do one of the most outstanding recent chapters in physiology. It is not so difficult to find space for the accomplishments in the field of organotherapy. This may seem strange, for it might be expected that from the great mass of new knowledge concerning reproductive physiology there should be a rich yield of facts translatable into therapeutic practice.

The best way to teach organotherapy is to teach endocrinology. Without some knowledge of the latter, it is utterly impossible for the physician to employ hormone products intelligently, with such knowledge he can at least know whether a given plan of endocrine treatment is rational and sound or whether it is palpably irrational and quite sure to be ineffective. This is not to say that treatment which seems quite rational is sure to be effective for this unfortunately is not true. It does mean, however, that certain methods of treatment can be carried out with no loss of dignity or self respect, while others will at once be rejected as obviously unsound.

The most effective method for correcting the evils and abuses of gynecologic organotherapy is to teach the members of our profession at least the elements of reproductive physiology. Feeling as I do about this, I am frank to say that I would much rather discuss reproductive endocrinology than gynecologic organotherapy, the subject that has been assigned to me. For a fuller discussion I may refer to several previous publications.¹

Thus far the chief contributions to therapy made by recent scientific investigations in this field have been of negative rather than of positive value. They have shown the incorrectness and often the absurdity of many of the older methods of gland treatment and the worthlessness of many of the preparations formerly so widely employed for this purpose. This, after all, has been no mean contribution.

If one looks back detachedly over the poorly marked road that has been traveled, it now seems clear that ovarian therapy got off to a bad start. It was "dat ole

Read before the General Scientific Meeting at the Eighty-Sixth Annual Session of the American Medical Association, Atlantic City, N. J., June 11, 1935.

dehbit" analogy which was responsible for the first efforts at ovarian therapy in the old Landau clinic in Berlin in 1894. Some years previously Murray and others had demonstrated the brilliant results of thyroid feeding in cases of thyroid hypofunction. Why, then, should not ovarian feeding give equally good results in the treatment of conditions of ovarian underfunction? This was the first false step, and it is appalling to think how many billions of ovarian tablets had to be ingested before the profession was convinced of the inefficacy of the method. As a matter of fact this grandiose therapeutic experiment would still be in progress had it not been for the cruel disillusionment emanating from the laboratories. That there is still a vogue for this form of treatment is an excellent illustration of the painful slowness with which new knowledge permeates professional practice.

With the discovery of the functional importance of the corpus luteum by Fraenkel in 1903, the new fad of corpus luteum therapy had to run its course as inevitably as a case of measles, side by side with the practice of giving ovarian tablets or capsules or, later, ovarian residue in one form or another. All these substances were rather costly to the patient, and the national cost of such medication would total a figure that would not be unimposing even in this day of stratospheric finance.

All this, of course, is "old stuff", but it is the stuff that forms the background of gynecologic organotherapy as we know it now, and it can no more be disregarded in an analysis of the latter than can tradition, folk lore or superstition in the development of our national mind. While the cold truth is that all these older preparations for oral administration are entirely or almost entirely inert, the person who believes they are no longer used, or that there are no longer doctors with pencils which reflexly write for ovarian tablets at the mere mention of any functional menstrual disorder, would believe that there are no longer people who carry horse-chestnuts in their pockets to ward off rheumatism.

An entirely new trend was given to ovarian therapy with the discovery of the follicle hormone, for here, for the first time, we were dealing with a purified principle of undoubted potency even in the cold glare of the laboratory. It is no wonder that the clinician, so completely lacking any satisfactory treatment in the very large class of functional gynecologic disorders, at once sat up and took notice, for here there seemed something tangible and intelligent to work with. There thus began another phase of ovarian organotherapy dealing with hormones rather than with gland preparations, but equally disappointing, and for reasons that could have been foretold at the time and were foretold by those who were at all familiar with the physiology of menstruation and with the differences which it exhibits from the estrous cycle in the lower animals.

To produce estrus in the lower animals, only one ovarian hormone that of the follicle is necessary, so that the administration of the latter in proper dosage may be expected to produce the phenomenon even in the castrated animal as it does. But to produce menstruation in the human female two ovarian hormones are necessary, that of the follicle and that of the corpus luteum, and they must be properly balanced in a quantitative way and must operate in a certain sequence. Furthermore they must be given in huge dosage, if they are to bring about in the uterus an actual simula-

tion of menstrual changes. This has been shown by experiments on castrated women, the adequate dosage being apparently from 200,000 to 300,000 mouse units of estrin and 60 rabbit units of progesterin. Parenthetically, it may be added that eighty human corpora lutea would be required to yield one rabbit unit of progesterin, for here, as with many other endocrine glands, there is a vast difference between storage and production capacities. Any one interested in arithmetic and knowing something of the present-day market value of these preparations can readily figure out that the reproduction of a single menstruation by this treatment would cost several hundred dollars.

Another woful shortcoming of ovarian therapy in cases of ovarian deficiency is the fact that it is purely substitutional and that it does not in any way start up the ovarian menstrual machinery. This is in keeping with the well known endocrinologic law that no ductless gland is stimulated by its own secretion. Moreover, the evidence indicates that excessive or prolonged estrin therapy actually inhibits the activity of the anterior hypophysis, on which depends the efficiency of the pelvic menstrual mechanism.

Still another factor, as I shall later reemphasize, is that estrin treatment in itself has no more stimulating effect on ovulation than it does on menstruation, so that its use in most cases of the sterility so often associated with amenorrhea is irrational and unsuccessful.

Finally, in the treatment of gynecologic disorders of various sorts with estrin, one must contend with the possible factor of antihormone production, which may perhaps explain the apparent refractoriness of the organism to long continued endocrine therapy. This bedeviling concept, recently suggested by Collip and his associates, is still too new and unconfirmed to justify its discussion except as a possibility to be contended with, as if there were not already enough such difficulties to plague the endocrinologist. One may be permitted a sigh of relief that recent investigations appear to indicate the incorrectness of the antihormone concept as applied to theelin.

In view of the dominance of the anterior hypophyseal lobe over gonadal function, is there any way in which a lazy or totally inactive pituitary may be restored to normal activity? If there were, the problem, at least so far as ovarian hypofunctional conditions are concerned, would be much simplified. In spite of the assurance with which primary ovarian deficiency is spoken of, it is probable that in the majority of such cases the ovary would be capable of responding to the pituitary stimulus if the latter were forthcoming. But there is no known way of stimulating anterior lobe activity except the rather empirical and uncertain method of irradiation. No one knows just how the latter acts or on what elements it produces its chief effect, so that its employment in functional disease can only be compared to the employment of the "alteratives" so popular with the saddle-bag practitioner of a former day.

For substitutional purposes pituitary substances are often employed by mouth, without benefit, according to the best available evidence, unless huge doses are employed, and even then there is considerable reason to doubt their efficacy. The anterior pituitary-like substances now so popular because of their undoubted gonadotropic effects in animals have been without noteworthy effect as substitutes for the deficient anterior pituitary hormones, as might perhaps be expected, since

they are now believed by most investigators to be chiefly of chorionic rather than of pituitary origin

These, then, together with thyroid extract, are practically all there is to work with in efforts at gynecologic organotherapy. Some of the commercial forms of these substances I have enumerated in a recent paper, so that I shall in this paper talk in the general terms of physiologic principles rather than the commercial preparations that actually or purportedly represent these principles. Since the writing of the paper referred to, there have been a few additions to the armamentarium of ovarian therapy. The chief changes in this field are (1) at least some reduction in price, (2) a growing tendency to adopt the international unit of dosage for estrin in place of the rat unit, which had been almost universally employed in this country, (3) the production of more potent estrin preparations, (4) the availability of commercial preparations of progesterin, and (5) an effort to prepare the anterior pituitary sex principles from the gland itself instead of utilizing the anterior pituitary-like principles found in the urine of pregnant women. While reports of the use of these newer preparations are beginning to appear in the literature, these have so far been too meager to justify any conclusions as to whether they will bring about any improvement in results. For reasons that I have discussed, no matter how much the ovarian hormone preparations are improved they would still fill only a limited need in most of the indications for which they have been recommended.

Since this review is to be an evaluation of the rationale or lack of rationale of present-day glandular therapy for gynecologic disorders, the most logical plan would seem to be to set forth my comments under the heads of the various conditions for which organotherapy has been recommended.

AMENORRHEA

As I have had occasion, in a recent paper in *THE JOURNAL*,² to discuss at length the use of estrogenic substances in the treatment of amenorrhea, only a brief epitome need here be included. Organotherapy is useful in the definitely hypothyroid cases but of little value in other types, and the latter make up by far the largest group. The old-fashioned tablets, capsules or powders of ovarian substance, ovarian residue and corpus luteum substance are practically inert, so that there is no excuse for their use at present. Estrogenic preparations, such as the commercial theelin or anniotin, have little value for reasons that I have already enumerated. If they are used for this indication, and there are probably few gynecologists who do not at times feel driven to this by the lack of any treatment more logical or more successful, they should be employed in very large doses if the patient can afford this. If economy makes necessary the usual small doses, there is little reason to expect good results, so that the treatment is to be looked on as little more than a placebo to the patient and a mental sop to the physician.

To be as nearly rational as possible under present conditions, the administration of estrogenic substances in amenorrhea should be immediately followed, with some overlapping, by the hypodermic administration of preparations of the gonadotropic substance from the urine of pregnancy, such as antuitrin-S or follutein, or one may try one of the progesterin preparations, which are beginning to appear. The most that can be hoped

for even then is a single menstrual period, so that the treatment would have to be repeated for each menstrual period, a plan that is obviously not practical and of which the patient will soon tire. She will usually then pass on to some other physician, who with incipient enthusiasm will tackle the problem along similar or even more ineffective lines. Every now and then she may have a period of bleeding, perhaps spontaneously or perhaps as a result of treatment, her physician at that time being made to glow with a pride and enthusiasm which commonly fades when the amenorrhea again recurs. The perseverance of many patients is amazing, their peregrinations being checked only after many years of disappointment, or by advancing years, or until they are fortunate enough to fall into the hands of a physician who will take the trouble to explain to them that amenorrhea in itself is harmless and that, unless the factor of the frequently associated sterility is the all important one, as it unfortunately often is, there is not much to be hoped for from ovarian organotherapy in its present state. My own policy in such cases is to emphasize to the patient that such problems are being intensively studied throughout the world and that it is quite possible that these studies may before long yield some more effective organotherapy than is now available.

DYSMENORRHEA

It is very probable, though not clearly established, that in some cases of primary dysmenorrhea the endocrinopathic factor is the important one. There are many physicians even now who treat such cases, and indeed any functional gynecologic disorder, with the older forms of desiccated ovarian or corpus luteum substances given orally. For this there is not the slightest excuse to be made. There are others who use the estrogenic substances, usually just because they are the up-to-date forms of giving the ovarian principles and not because any one has any idea as to how they can do good in dysmenorrhea. The preponderance of what little evidence there is on the subject would indicate that they might do harm, for most investigators believe that estrin increases and progesterin decreases uterine contractility. On this basis there seems to be some reason to employ progesterin or the pregnancy urine preparations as a part of the treatment of primary dysmenorrhea. Far more important in the present state of organotherapy is an effort to correct the constitutional, environmental or psychogenic factors that are so often concerned in the causation of dysmenorrhea.

FUNCTIONAL UTERINE BLEEDING

For functional uterine bleeding, organotherapy appears to have established itself as of some value, although our imperfect knowledge concerning endocrine mechanisms entails a certain degree of empiricism in such treatment. Furthermore, the results are far from uniformly good. The largest group of functional cases are those characterized by a failure of ovulation, with abnormal persistence of estrin activity and with absence of the corpus luteum and its characteristic hormone, progesterin. This syndrome occurs most frequently in women approaching the menopausal epoch but is encountered at any age during reproductive life and is frequent in girls during the pubertal and adolescent years. The endometrium in such patients shows a greater or less degree of proliferative but always non-secretory change and in the typical case presents the characteristic Swiss cheese gland pattern of hyperplasia.

² Novak, Emil. The Therapeutic Use of Estrogenic Substances. J. A. M. A. 104: 1815 (May 18) 1935.

Mild cases of this disorder are frequent, and often the endocrine balance is spontaneously readjusted without treatment of any kind. When the bleeding is severe, organotherapy is indicated, and in very young individuals, in whom there is no reason to fear cancer, this need not be preceded by diagnostic curettage, though pelvic examination, either vaginal or rectal, is always wise. The most frequently helpful treatment is with one of the anterior pituitary-like preparations made from the urine of pregnant women, the two chief commercial forms being antuitrin-S (Parke, Davis & Co.) and follutein (E. R. Squibb & Sons). These were originally suggested because of their luteinizing effects on the ovaries of laboratory animals, in the hope that they might have a similar effect on the human ovary, which might thus be stimulated to supply the progesterin deficiency. Progesterin itself would be more rational and probably more effective if an unquestionably active preparation were available for clinical use. Although it is now known that these anterior pituitary-like substances do not in the human being bring about luteinization, the fact remains that in many cases they are useful in checking or controlling bleeding. Just how this occurs is not known though it is probably dependent on some interaction between the ovarian and pituitary secretions. There seems to be no doubt that the underlying disturbance in such cases involves the anterior hypophyseal lobe, so important as the regulator of ovarian function.

When the pregnancy urine hormones are used in the treatment of functional hemorrhage it seems best to withhold them until the onset of a bleeding phase, for often the bleeding is periodic. From 100 to 200 units may then be given intramuscularly each day, for from one or two to five or six days, depending on the severity of the bleeding and the effect of the treatment. If bleeding is of the prolonged metrorrhagic type, treatment should be commenced at once. When those preparations alone are ineffective, the simultaneous daily injection of the ordinary posterior lobe extracts, in doses of from 0.5 to 1 cc., will sometimes enhance their value.

In women near middle life, and especially when the bleeding has been prolonged and free, curettage is advisable, because it usually checks the bleeding at least temporarily, and because it eliminates more serious intra-uterine lesions, such as cancer. When bleeding recurs after curettage, it may be treated organotherapeutically, according to the foregoing plan, but, if the woman is approaching the menopausal age, the sensible plan is to abolish the menstrual function by means of x-rays or radium. The latter should not be employed in young women except as a last resort, and then only by those sufficiently expert to regulate the dosage in such a way as to minimize the risks of permanent abolition of the reproductive and menstrual functions.

In some cases of functional bleeding, especially when there is definite evidence of hypothyroidism, thyroid extract is indicated, and it may be of value in the relief of the bleeding though such cases have not been numerous in my experience. Many other forms of organotherapy have been suggested, such as the use of estrin, parathyroid extract, insulin or mammary extracts but neither the rationale nor the results of such plans have commended them for general usage. The plan that I have suggested leaves much to be desired, and its general results are not at all consistent, but it has been detailed because the available evidence warrants the statement that it gives better results than any other

plan of organotherapy. There is little question that it will sooner or later be superseded by some more effective plan, perhaps by the substitutional use of progesterin, especially since there now seems to be a real hope for the synthetic preparation of the latter.

VASOMOTOR MENOPAUSAL SYMPTOMS

Although various explanations have been suggested for the mechanism of the curious vasomotor flushes, sweats and heat flushes that characterize the menopause, nothing of a definite nature is known. There is, however, little doubt that the immediate factor is the withdrawal of ovarian function, and considerable evidence to indicate that the most important factor is the cessation or marked diminution of estrin production. I need mention only the following observations in support of this view. 1. These vasomotor phenomena are usually mild or absent altogether in that phase of the menopause during which estrin is present in excessive amount, especially when this excess is expressed in the form of functional uterine bleeding. They are more apt to be troublesome in the stage of estrin deficiency, which, according to Zondek, follows that of excess. 2. In a number of cases of granulosa-cell carcinoma in women many years after a normal menopause, which had been accompanied by characteristic vasomotor symptoms, a second menopause, with again characteristic symptoms, has been observed. These tumors characteristically produce only estrogenic substance.

It is scarcely necessary to add that cessation or marked diminution of ovarian function is accompanied by striking changes in the anterior lobe, changes which, especially in the surgical menopause, are quite similar to the well known castration hypertrophy of the anterior lobe so well established by laboratory experiments. It seems quite possible that these pituitary changes, with some unknown repercussion through the cerebral and sympathetic centers, are responsible for the vasomotor phenomena, though one can only speculate as to the pathways and mechanism that are involved. But the fact remains that the estrin deficiency, especially if sharp or sudden, is the conspicuous hormone phenomenon associated with such symptoms. Hence the administration of this hormone in an effort to ease the patient over the transition phase seems logical when symptoms are sufficiently severe.

There is no phase of woman's life concerning which the public cherishes so many incorrect ideas as it does concerning the change of life. Hence the apprehensiveness with which many women approach this epoch. A physician can render his women patients a great service by explaining the normality of this phase, stressing the fact that in most cases no medication of any kind is necessary, because of the absence or mildness of the symptoms. Much can also be accomplished by insistence on the avoidance, so far as possible, of stress, worry and anxiety as well as the importance of maintaining physical health on as high a level as possible by such measures as rest and recreation. Simple nerve sedatives, such as the bromides, are often valuable adjuvants and may be all that is required in the way of medicine. In spite of all this, a minority of women are made very miserable for many months, and even a number of years because of the severity of the vasomotor symptoms. What can be done for these? If there is anything more nearly rational or more effective than estrin therapy now available for this indication, I do not know of it. With full regard for the necessity of eliminating the subjective factor in the

evaluation of results, and with full knowledge of the lack of brilliance in these results, my experience has been that many patients can be very materially helped by this plan of treatment, combined with the general measures already mentioned.

The admittedly poor results of ovarian therapy in general, and its lack of rationale in so many of the indications for which it has been employed, are no doubt responsible for the completely nihilistic attitude expressed by some writers, concerning even the few indications in which the hormone does not seem illogical or wholly ineffective. Without the slightest feeling of cocksureness on the subject, I for one expect to employ hormone therapy as a part of the management of some menopausal cases until a more effective or more rational method becomes available. I have an idea that most of the scoffers will do the same.

There would seem to be no excuse for the oral administration of the older forms of desiccated preparations of whole ovary, corpus luteum, or ovarian residue when commercial preparations of the hormone, with demonstrated laboratory potency, are now available. This hormone can be given either hypodermically or orally, the effective dose by the latter route being about five times that required by the hypodermic method. The available preparations, the doses and the general plan of treatment suitable for menopausal cases have been fully discussed in a recent paper, so that they need not be detailed again here.

STERILITY

While our knowledge of endocrine factors in sterility is very meager, there is no doubt that they play an important part in many cases of this frequently distressing female ailment. It seems hardly necessary to say that such an etiology should never be assumed until a thorough study of the male and female partners has eliminated all the other more common possible causes of the condition. If hypothyroidism is demonstrated in either partner, appropriate thyroid therapy is clearly indicated and pregnancy not infrequently follows. Even if the basal metabolism rate is normal there is no objection to small doses of thyroid, and even here good results are at times observed. When, as is so often the case the sterility is associated with an endocrinopathic amenorrhea of what might be called the cerebrohypophyseogonadal variety, the treatment is that of the latter, and the results are equally poor. In this group thyroid therapy is likewise commonly employed. It is probably of more frequent value than the administration of the ovarian or gonadotropic preparations so widely used.

Two other endocrine aspects of sterility may at least be mentioned. One is the possible absence of ovulation even though menstruation is essentially normal in rhythm and amount, and even more if it is somewhat irregular and free. That in some of these cases the sterility is due simply to the fact that no eggs are being given off by the ovaries no longer permits of doubt, as I have discussed in a recent article. But we do not as yet know what the actual cause of ovulation is. For that matter, it seems likely that it is neither the follicle-ripening gonadotropic hormone (prolan A), as some suggest nor the luteinizing hormone (prolan B), as others believe, but that it is dependent on some delicate quantitative balance between these two substances. Hence the present difficulty of correcting this anovulatory mechanism, and the fact that one must for the

present resort to such experimental therapeutic measures as the administration of the prolan-containing preparations at or near the usual time of ovulation.

Finally, even if the egg is given off, there is no certainty that it is fertilizable. The doctrine of "defective germ plasma" seems to have gained the acceptance of the most conservative embryologists. If the inferiority of the egg is not quite so pronounced, it may, so to speak, take the sperm charge, but "idiopathic" abortion or miscarriage takes place at one stage or another of pregnancy. If the germ plasma is still less inferior in quality the pregnancy may go to term, with stillbirth or death shortly after birth, while in the ideal cell union the germinal momentum is sufficiently strong to carry the gestation product through the usual human span. Needless to say the quality of the male germ is just as important as that of the female. The fertilized egg is the resultant of the fertilization capacities of both male and female partners, and in either one of these sterility may be only relative instead of absolute. From a practical standpoint, the only suggestion that can be made when such a factor as defective ova is suspected is to endeavor to improve the constitutional and endocrine status of the couple in every way possible. As regards the constitutional element, this often means the correction of such factors as diet, psychic conditions and overwork.

GONORRHEAL VULVOVAGINITIS OF CHILDREN

The treatment of the troublesome and frequent gonorrheal vulvovaginitis of children has long been a *bête noire* to gynecologists, so that there has been considerable interest in the suggestion of Lewis that estrogenic therapy might, through its biologic effect on the vaginal mucosa of the child's vagina, be of therapeutic value in this form of vulvovaginitis. Suffice it here to say as I have done more in detail elsewhere, that the treatment seems rational and that, in the light of such reports as have been made available, it merits continued usage, at least until its efficacy can be more satisfactorily proved or disproved. As the method is now being tried out fairly extensively, it should not be long before more definite conclusions than are as yet available can be arrived at. Studies now being made in the outpatient clinic at the Johns Hopkins Clinic by TeLinde and Brawner indicate not only the usual effectiveness of the treatment but that the most effective way to administer the hormone is by the vaginal route, through the use of vaginal cones containing the active principle.

OTHER INDICATIONS

There are a number of other indications for which organotherapy has been suggested and employed, but these need not be discussed here, because of the indefiniteness of the indications and the poorness of the results. Moreover, this poorly defined group has been briefly discussed in my previous paper. In this I also described the employment of the anterior pituitary-like hormones of pregnancy urine in the treatment of undescended testis. In this condition, in which surgical treatment is not always as successful as might be wished, the reported results justify the statement that operation should not be resorted to without first trying the organotherapeutic plan.

SUMMARY AND COMMENT

Sifting out the worthwhile evidence available on the general subject therefore, it may be concluded that organotherapy is apparently of value in the treatment

of functional bleeding and of the menopausal symptoms. Ovarian therapy seems worthless in the treatment of amenorrhea, though thyroid treatment is of value in an indeterminate though apparently not large proportion of cases. In dysmenorrhea the use of the anterior pituitary-like pregnancy hormones is helpful in some cases, though the correction of constitutional, psychic and environmental factors should never be overlooked and is far more frequently important for successful results. The use of organ extracts, especially thyroid, is fully justified in cases of sterility, but only after thorough consideration and, if possible, elimination of other etiologic factors. The available evidence indicates the value of organotherapy in cases of gonorrheal vulvovaginitis in children, and for the nongynecologic indication of undescended testes.

All in all, therefore, no great hardship would be worked on the female sex if ovarian organotherapy were suddenly blotted out. Indeed, this might not be undesirable if the new therapy that would be sure to arise could be built up on the substantial basis of what has actually been established in recent years concerning reproductive physiology, and what is reasonably sure to be learned in the years just ahead of us. Such a dream of starting all over again is just as utopian in this as in other fields of therapy, for always the harassed physician is faced with the necessity of doing the best he can under existing conditions when, as is so commonly the case, a scientifically ideal plan is not possible. But no physician can treat endocrine disorders intelligently unless he knows something of endocrine functions and interrelationships. The subject is admittedly vast, confusing and rapidly changing. There is thus a temptation for the busy doctor to dismiss the whole thing as a hopeless muddle and to depend on the literature of manufacturing houses for quick and often superficial information on the subject. And yet it is easy, without great effort, for every physician to familiarize himself with the essential elements of the subject through the numerous summarizing reviews that have appeared, none being better than the series of articles on "Glandular Physiology and Therapy" which have just been published in *THE JOURNAL*. In this field almost more than any other those qualified to do so can render a genuine service by summarizing, clarifying and appraising the subject for the benefit of those who through lack of time or opportunity, cannot otherwise keep in touch with the rapid developments in this field.

26 East Preston Street

Sir Patrick Manson's Diary—Manson commenced his Diary in June 1877 and continued to make entries therein with commendable regularity for another twenty years. The Diary is a plain ledger bound in buckram, and appears to have been acquired by Manson on his advent to Amoy for on the outer cover can still be deciphered Imperial Maritime Customs Amoy. The book measures 13 by 8 inches and contains 612 closely written pages. In these pages there are gathered together scattered observations on the main subjects for which Manson's name became world famous. It was apparently his habit to record his observations and experiments daily in an orderly fashion and to keep transcripts of all the letters he wrote to correspondents such as Timothy Lewis Spencer Cobbold, Leuckart Lister and the *Lancet*. Inserted too between these pages are numerous original drawings. The Diary is therefore replete with scientific historic and human associations. Naturally the main interest radiates round his first love—filariasis—Manson Bahr Philip. A Commentary on the Diary Kept by Patrick Manson in China and Now Conserved at Manson House, Tr Roy Soc Trop Med & Hyg 29 79 (June) 1935.

GLANDULAR PHYSIOLOGY AND THERAPY

COMMERCIAL GLANDULAR PRODUCTS

MORTON S. BISKIND, M.D.

CHICAGO

NOTE—This article concludes a series of thirty-two articles on glandular physiology and therapy by various authors, published under the auspices of the Council on Pharmacy and Chemistry. The series of articles will be published in book form.—Ed

Perhaps no group of pharmaceutical preparations in recent years has been the subject of such extravagant claims as that comprising allegedly active materials derived from various glands, nonglandular organs and body fluids. Hardly a tissue or fluid of the body has escaped desiccation or extraction, substances so obtained are marketed in pills, tablets, capsules, vials and ampules for introduction into the body by every conceivable route. Only a small percentage of the many preparations are known to contain active material, and with the few exceptions (thyroid, liver, stomach, adrenal cortex, and some estrogenic principles) discussed later, the products administered *by mouth* have little effect even if they do contain some active principle or principles¹. The active substances are either destroyed by the digestive juices or if not broken down they may not be absorbed from the intestine. An excellent example is the one presented by Evans² who, with Long, administered fresh pituitary glands to rats as the sole source of food without the slightest detectable acceleration of growth, a much smaller amount of material properly extracted and administered parenterally is known greatly to enhance the rate of growth. Thus glandular therapy by the oral route is in general quite limited, even when effective it is usually wasteful, as much more material must be used owing to poor absorption. However, when dealing with relatively impure products that may have toxic effects on parenteral injection it may be preferable to administer the preparation orally, if feasible. An example of this is adrenal cortex extract³.

Purification, particularly important for preparations intended for parenteral use, involves many difficulties. Chemical treatment may result in degradation products, whether or not a principle obtained by extraction actually exists as such in the gland from which it is derived is often a matter for speculation. Only a few substances have so far been obtained in crystalline form, by far the great majority of the remaining products are more or less contaminated with other active or inactive substances. Effects ascribed to an alleged active principle may be caused by pharmacologically active contaminants. These contaminants may also be important from the standpoint of toxicology, a number

¹ The Council on Pharmacy and Chemistry has omitted from V N R all desiccated ovarian preparations at one time thought to be active by mouth (Desiccated Ovarian Preparations for Oral Administration Omitted from V N R Report of the Council on Pharmacy and Chemistry J A M A 94 1997 (June 21) 1930). With the exception of thyroid and some liver and stomach preparations no glandular product for oral use stands accepted by the Council.

of untoward reactions from the administration of glandular products have been reported⁴

Assay involves still further difficulties. The majority of methods employed are biologic, the effect of a given preparation is determined on some physiologic function in a test animal. At best biologic assay entails very large errors, sometimes as much as 1,000 per cent.⁵ In addition, the effect produced in the test animal that serves as the measure of potency may not necessarily be the effect desired or the effect that occurs in the human being who is treated with the preparation in question. For instance, a comparison of two estrogenic substances by the Allen-Doisy vaginal cornification test has no necessary bearing on the relative effectiveness of the two preparations in relieving the symptoms of the menopause in a woman, or an effect occurring in a test animal, such as the rise in blood pressure following the administration of a posterior pituitary extract to an anesthetized dog or cat, may not occur at all in the normal human being.⁶ Species differences also play a large part in making more difficult the interpretation of assay data. This is particularly true with gonadotropic and estrogenic products. Recent studies have emphasized the great differences in the physiology of the reproductive tracts in various species of animals. The only animal available for experimentation having a menstrual cycle similar to that of the human being is the *Macacus monkey*. Yet this animal is not used for assay. Most, if not all, the products belonging to this class are assayed on mice, rats or rabbits. Thus, the stated activity of a great many glandular products may be considered as no more than rough approximations. In addition, questions of deterioration in the interim between assay and use and of differences in rates of absorption and excretion of the active principle or principles make endocrine therapy with commercial products even more uncertain. Even when active products are used, consideration of the possible production of antihormones, which have been discussed at length by several authors in this series,⁷ enjoins caution in glandular therapy. From the practical standpoint of clinical use, the important factor is that the phenomenon described by Collip and his co-workers actually does occur with certain glandular products. Questions of the nature and mechanism of production of antihormones are secondary, for the time being these need concern only the physiologists.

Much confusion arises from the present deplorable state of endocrinologic nomenclature, this is particularly true with respect to commercial products. As stated in a recent editorial in *THE JOURNAL*,⁸ "In addi-

tion to the many terms invented from time to time by research workers in many parts of the world, the situation has been made even more difficult by the tendency of each of a number of commercial firms to register its own trade mark for a product to which otherwise, in most cases, it has no proprietary claim. The language of medicine appears to have been more burdened than enriched by the new nomenclature." Not infrequently the physician is confronted with a series of products purporting to be similar but sold under widely different names, or with other products unquestionably different but marketed under similar names. Examples of the former are too numerous to require specific citation, as an instance of the latter, three preparations of Parke, Davis & Co. may be mentioned "antuitrin," apparently a "soup-like" extract of the anterior pituitary, "antuitrin-S," an extract of the urine of pregnant women containing the pituitary-like gonadotropic factor, and "antuitrin-G," an extract of the anterior pituitary said to contain the growth hormone. That these three preparations are sometimes confused one with another is not surprising. Another example is supplied by the Schering Corporation, which markets two different estrogenic preparations, "progynon" and "progynon-B."

With an understanding of the many serious difficulties involved in the use of commercial glandular products, detailed consideration may now be given to the products themselves. It is inevitable that many products marketed in various parts of the world will be omitted, it is practically impossible to consider in detail all the products on the market within a reasonable space. Many of the preparations are such as to require no serious consideration, they fall into various classes of useless pharmaceuticals the characteristics of which are evident. Among these are combinations of extracts or of desiccated material from two or more glands. With one or two exceptions (such as combinations of liver and stomach for the treatment of pernicious anemia) these appear at present to be irrational. The great majority of pluriglandular products on the market are simply unstandardized (from the standpoint of their content of active principles) empirical mixtures, many are intended for administration by mouth, by which route the alleged active principles would in most cases not be effective. In addition, mixtures that do contain active material, and are recommended for administration by a route by which they may be expected to be effective, will contain the active substances in approximately fixed (and after a little aging, in unknown) proportions. Also, the effects of chemical interaction of different principles in solution are practically unknown. It seems much more rational to employ two or more separate extracts (each standardized as to its content of active substance) if these should be indicated. It is sufficiently confusing at best that a considerable number of the available extracts of single glands contain more than one active principle to add to the relatively impure preparations now available the products of still other glands is to compound the confusion.

The fact that the description of a product does not appear in the following should not be construed as necessarily indicating that it is considered to be a useless preparation. Furthermore, the amount of space devoted to describing the various preparations may not

be in proportion to their relative importance. A number of new and comparatively untried products are discussed at length, as descriptive information on them may not easily be available elsewhere. Well known substances described in the Pharmacopeia or in New and Nonofficial Remedies are mentioned briefly or not at all.

Emphasis will be confined chiefly to the more important products marketed in the United States. Only those designated with the suffix N N R are accepted by the Council on Pharmacy and Chemistry.

ANTERIOR PITUITARY

Pituitary preparations intended for oral use will not be discussed, as there is no satisfactory evidence that these are effective by mouth.

Growth Hormone—Commercial preparations containing the anterior pituitary growth hormone in solution, free from other active principles, are not yet available. In general this appears to be true of all the pituitary extracts, even the relatively pure products contain contaminating substances in greater or less amount. The physiologic action and the therapeutic indications and effects of preparations containing the growth hormone are considered in the papers by Evans² and by Novak³ in this series. The clinical use of these products is still in the experimental stage. Caution is therefore indicated.

The presence of active principles other than the growth-promoting factor must be kept in mind as untoward effects may occur owing to stimulation of the thyroid gonads¹⁰ or other organs. Three products claimed to contain the growth hormone are available on the American market.

Anterior Pituitary Extract Squibb E. R. Squibb & Sons. This is said to contain the growth-promoting factor and, in addition, the gonadotropic and thyrotropic principles of the hypophysis. It is assayed for its content of growth hormone only. Adult female rats weighing 250 ± 25 Gm are injected daily for ten successive days; one rat unit is the daily dose necessary to cause an increase in body weight of 10 per cent in an eleven day period. Anterior pituitary extract Squibb is marketed in 10 cc rubber-diaphragm-capped vials containing 10 rat units in each cubic centimeter. As the potency in terms of growth hormone appears to be approximately equal to that of antuitrin G, the same dosage statement would probably apply. The dosage recommended by the manufacturer is from 0.5 to 5 cc, intramuscularly three times a week.

Antuitrin G Parke Davis & Co. This preparation is stated to contain the growth hormone without significant amounts of the gonadotropic, thyrotropic or adrenotropic factors. It is doubtful whether antuitrin-G may for practical purposes be considered free of these factors; however, as no assay data are available as to the content of these principles, the product is assayed for its content of growth hormone by its effect on the growth of adult female rats from 6 to 7 months of age: one rat unit is the minimal daily amount which when injected intraperitoneally in two divided doses will cause an average daily increase of 1 per cent in body weight over a period of ten days. Antuitrin-G is marketed in 20 cc rubber-diaphragm capped vials each cubic centimeter containing 10 rat units. The optimum dosage is not definitely established; antuitrin-G has been administered preferably intramuscularly in doses varying from 1 to 3 cc, two or three times a week. The dosage recommended by the manufacturer is from 6 to 10 cc, per week in divided doses of 2 to 5 cc.

Phyone, Wilson Laboratories. Information is not available as to the method of preparation and standardization of this product, or as to the forms in which it is marketed.^{10a}

Gonadotropic Principles—These are of two types, known, for want of better terms, as follicle stimulating and luteinizing. Commercial preparations in general contain mixtures of the two (and probably greater or smaller amounts of other factors as well). As yet there are few controlled clinical studies with the gonadostimulating extracts of the pituitary itself, most of those so far reported have been made with extracts of pregnancy urine or placenta. The effects of the latter, as already pointed out in several articles of this series,¹¹ are not equivalent to those produced by products obtained from the pituitary. In view of studies indicating that a persistent refractory state¹² of the ovaries of experimental animals may be produced by pituitary extracts, the commercial preparations should be employed clinically only when their known physiologic effects are fully understood and then with caution. The indications, contraindications and dosage are at present poorly defined.

Preparations derived from pituitary tissue

Gynatrin G D Searle & Co. This is said to contain the two gonadotropic factors of the pituitary; the presence and amount of other factors are not stated. Gynatrin is said to be assayed and standardized as follows: A rat unit is defined as the smallest amount which when divided into six equal parts injected over a period of three days into immature female rats less than 30 days old and weighing from 35 to 40 Gm will by the fifth day produce follicular maturation and luteinization of the ovaries and a marked increase in the size of ovaries and uterus in at least 60 per cent of animals so treated. Gynatrin is marketed in 5 and 15 cc rubber-diaphragm-capped vials, each cubic centimeter containing 100 rat units. The dosage recommended by the manufacturer is from 0.1 to 2 cc, administered preferably intramuscularly. As already stated, the indications, contraindications and dosage of this preparation are not yet well defined.

Prephysin-Chappel Chappel Bros, Inc. This is said to contain the follicle stimulating principle of the pituitary gland, including small quantities of the luteinizing factor prepared by the method of Fevold and his collaborators as modified by Meyer and Fevold. The presence and amount of other factors are not stated. Prephysin is said to be standardized as follows: One rat unit is that amount which, divided into six equal parts and injected over a period of three days into immature female rats 22 days old produces an increase in the weight of the ovaries of from 50 to 100 per cent by the end of the fifth day. The product is marketed in 5 cc rubber-diaphragm capped vials each cubic centimeter containing 25 rat units. The dosage recommended by the manufacturer is from 0.5 to 1 cc. Caution is necessary with regard to overdosage.

A number of products purporting to contain the gonadotropic factors of the pituitary are made by European firms. The available descriptions of these products are meager and in some cases it is not clear whether a given preparation in question is derived from the pituitary, the placenta or the urine of pregnancy. Infor-

^{10a} According to Evans² phyone prepared by the method of Van Dyke and Wallen Lawrence is contaminated not only with much inert protein but also with recognizable amounts of gonadotropic and thyrotropic hormones and traces of the lactogenic substance. Available literature does not indicate to what extent this applies to the Wilson product.

¹⁰ Evans² Novak³.

mation as to the methods of standardization is in practically all cases insufficient. Hence these will not be considered in detail.¹³

Commercial preparations containing the lactogenic,¹⁴ blood sugar-raising¹⁵ or other principles of the pituitary more or less free of contaminating factors are not yet available. Investigations have not yet reached the stage at which the administration of such products to patients would be warranted, even if they were available.

A number of firms market "soup-like" extracts of the anterior pituitary. An example of these is antuitrin (without the qualifying S or G), most firms do not employ trade names for these products. The number, nature and potency of the active principles (if any) in such preparations is in general not known. The available evidence indicates that these are usually not assayed but are adjusted to represent a certain weight of fresh or dried gland. Clinical use of products of this type rests on an empirical basis only, their employment should be deprecated.

ANTERIOR PITUITARY-LIKE PREPARATIONS

Extracts from the urine of pregnancy or placenta are available on the market under various names. The relation of such products to those derived from the pituitary itself has already been discussed in this series.

Antophysin, Winthrop Chemical Company. This preparation unfortunately is marketed in such a way as to create the impression that it is derived from the pituitary. However it is described in recent advertising circulars issued by the firm as "anterior pituitary-like gonadotropic hormone." It is therefore obvious that this product is obtained either from the urine of pregnancy, the placenta or both. The source, however, as well as the method of standardization is not stated. Antophysin is marketed in ampules containing a soluble powder, 100 or 500 rat units together with ampules of distilled water for dissolving the powder before injection. Intramuscular injection is employed. The product is also marketed in tablets for oral administration, but there is no satisfactory evidence that such tablets would be active by mouth in human beings.

Antuitrin-S Parke Davis & Co. This product is extracted from the urine of pregnancy. It is stated to be standardized as follows: One rat unit is the minimal amount which when divided into six doses injected subcutaneously over a period of three days, will produce corpora lutea in the ovaries of 26 day old rats by the end of ninety-six to 100 hours. Antuitrin-S is marketed in rubber-diaphragm-capped vials containing 10 cc., each cubic centimeter contains 100 rat units.

A P L, Ayerst McKenna and Harrison. This preparation contains gonadotropic substance derived from the placenta by the method of Collip. It is standardized as follows: One "biological day-unit" is the minimal amount which when administered subcutaneously daily for three days to immature rats (from 18 to 21 days old and weighing from 20 to 30 Gm) will produce a vaginal estrous reaction within 120 hours after the first injection in 50 per cent of the animals. A P L is marketed in 5 cc. rubber-diaphragm-capped vials, each cubic centimeter contains 100 "biological day-units."

13 Descriptions of these products given in Gehe's Codex for instance are not adequate to serve as a basis for the intelligent use of any of these products. If such preparations are employed, definite information should be obtained from the manufacturer in each case as to source, method of standardization and presence of active principles other than the one assayed for standardization. As the use of all these products is in an experimental stage it seems best to employ the products of firms in this country in order that information may more readily be obtained.

14 While E. R. Squibb & Sons announced some time ago that it would shortly market a lactogenic extract of the pituitary, no subsequent announcement appears to have been made by the firm. It appears from the recent report by Werner¹⁶ that the efforts of this firm to produce an active and relatively pure preparation of prolactin have not yet succeeded. Werner was unable to induce lactation in women with the Squibb extract; severe local and systemic reactions occurred.

15 Praephyson Promonta (Hamburg, Germany) has been claimed to contain the blood sugar raising principle of the anterior pituitary. However, if it does, other factors are unquestionably present as well.

Follutein, E. R. Squibb & Sons. Follutein contains the gonadotropic factor extracted from the urine of pregnancy. It is standardized as follows: One rat unit is the minimum amount which, given to immature rats 30 days old, in six injections on three consecutive days, produces mature follicles, hemorrhagic follicles and corpora lutea in the ovaries within 100 hours after the first injection. The product is marketed in a syringe containing 1 cc. of a glycerin solution (1,250 rat units), together with a rubber-diaphragm-capped vial containing 9 cc. of distilled water. Before use the contents of the syringe are injected into the vial, the mixture (which, according to the firm, should be kept refrigerated and used within three weeks) contains 125 rat units in each cubic centimeter.

POSTERIOR PITUITARY

The extract of the posterior lobe of the pituitary most commonly employed is that described in the U. S. Pharmacopeia. Hence this need not be discussed here. Some firms market extracts of twice the potency of the U. S. P. product, none of these more potent preparations stand accepted by the Council on Pharmacy and Chemistry for New and Nonofficial Remedies.¹⁶ There seems to be little excuse for marketing the more active extracts, as the preparations of U. S. P. potency are sufficiently effective and the former may be dangerous if employed inadvertently for obstetric use.

Two preparations described in New and Nonofficial Remedies may be mentioned briefly.

Pitocin, N. N. R., Parke, Davis & Co. An extract of the posterior lobe of the pituitary having an oxytocic effect (10 units in each cubic centimeter) equal to that of U. S. P. solution of pituitary, but less than 0.5 unit per cubic centimeter of pressor activity.

Pitressin, N. N. R., Parke Davis & Co. An extract of the posterior lobe of the pituitary containing the pressor and diuretic-antidiuretic principle or principles in the same concentration (10 units in each cubic centimeter) as that in U. S. P. solution of pituitary but with less than 0.5 unit per cubic centimeter of oxytocic activity.¹⁷

ESTROGENIC PREPARATIONS

Much confusion exists not only as to the nature, sources, potency and effects of the estrus-producing products but also as to their clinical indications. It should be emphasized that none of the known potent preparations are derived from ovary and that there is no satisfactory evidence to indicate that any of the preparations actually contain the ovarian follicular hormone or hormones. Consequently it is not warranted to speak of estrus-inducing principles obtained from the urine of pregnancy, placenta or amniotic fluid or by chemical alteration of any of these factors as "ovarian follicular hormone." Nor is the commonly used "(o)estrin" a satisfactory generic term for all these products. Estrin has been identified both with the specific crystalline compound known as theolol¹⁸ and with the chemical nucleus of compounds of this group, thus theelin is known as "ketohydroxyestrin" and theelol as "trihydroxyestrin." Estrin cannot be both the compound itself and the chemical nucleus of the substance, much as caffeine cannot be both xanthine

16 Report of the Council on Pharmacy and Chemistry (omission from N. N. R. of all posterior pituitary extracts differing from pharmacopeial potency) J. A. M. A. 93:524 (Aug. 17) 1929.

17 It will be noted that the strength of pitressin as described here is one-half that stated in N. N. R. 1935. The potency has recently been changed to make it accord with that of U. S. P. solution of pituitary with respect to the amount of pressor principle.

18 Dowsy, E. A. Chapter X (page 494) of Sex and Internal Secretions (Edgar Allen, editor) Baltimore: Williams & Wilkins Company, 1932.

and trimethylanthine. The chemical nomenclature proposed for the estrogenic and related substances by a British group of investigators¹⁹ has a number of features to commend it. None of the proposed chemical names, of course, are applicable to estrogenic principles the chemical nature of which is unknown. For the time being, therefore, it is best to refer to these simply as "estrogenic substances."

The question of the relative potency of the estrogenic products is in an unsatisfactory state, owing to inherent variability of test animals, to differences in

Fig 1—Theelin

Fig 2—Theelol

species sensitivity, to lack of uniformity in technique of conducting the assays and to the use of three different units, mouse, rat and international unit. Fortunately the latter is superseding the two former, although confusion continues to exist because various manufacturers employ different ratios for the equivalence of rat, mouse and international units and because they do not state which animal is used for assay against the international standard²⁰. The international unit is defined by the Permanent Commission on Biological Standardisation of the Health Organisation of the League of Nations²¹ as the estrus-producing activity contained in 0.1 microgram (one ten-millionth of a gram) of a standard preparation of theelin, this being approximately one-third the original rat unit of activity as defined by Allen and Doisy. A discussion of the various techniques of assay appears in the report of the Council on Pharmacy and Chemistry.⁵

The commercial products that represent crystalline material belong to three types, with proposed formulas (based on the formula for sterols suggested by Rosenheim and King) as follows:²²

(1) 3-hydroxy-17-keto-1,3,5-estratriene,¹⁰ ketohydroxyestrin, theelin, estrone, the compound used as the international standard (fig 1).

Examples: Theelin, Parke, Davis & Co. oestroform,²³ British Drug Houses, folliculin menformon,

Organon Laboratories (though apparently the latter product is not reduced to crystalline form during manufacture it is said to contain theelin as its active principle).

(2) 3, 16, 17-trihydroxy-1, 3, 5-estratriene,¹⁰ trihydroxyestrin, theelol, estriol (fig 2).

Example: Theelol, Parke, Davis & Co. Another product, emmenin, Ayerst, McKenna and Harrison, probably belongs in this group, while it is not reduced to a crystalline state during manufacture, it is said to represent a complex of theelol.²⁴

(3) The benzoate of 3, 17-dihydroxy-1, 3, 5-estratriene,¹⁰ the benzoate of estradiol (the hydroxyl group in the 3 position is replaced by benzoate forming 3-benzoate 17-hydroxy-1, 3, 5-estratriene^{24a}), hydroxyestrin benzoate (fig 3).

Examples: Progynon-B, Schering Corporation, dimenformon,²⁵ Organon Laboratories.

The three compounds differ considerably in a number of respects in their effects on test animals. To what extent these differences are reflected in the clinical use of these substances is unknown. It should be remembered that the commercial preparations are assayed according to the vaginal cornification test of Allen and Doisy in mice or rats. It does not follow that two preparations equally effective in producing vaginal cornification in animals will be equally effective in relieving some of the castration phenomena, for instance, in women, only in the treatment of gonorrheal vaginitis in children is cornification of the vaginal mucous membrane the desired clinical result.

Questions of the use of oily in preference to aqueous solutions, and of absorption, distribution and excretion of estrogenic principles are considered elsewhere²⁵ in this series and need not be discussed here.

Amniotin, E. R. Squibb & Sons. This is an estrogenic preparation originally derived from amniotic fluid, it is not reduced to the crystalline state during manufacture. More recently, according to the firm, the urine of pregnant mares has served as an added source of active material.

Fig 3—Progynon B

Dosage forms: Amniotin in Oil. Marketed in 1 cc glass ampules containing amniotin in corn oil in potencies of either 2,000 or 8,000 international units in each cubic centimeter, for intramuscular administration.

Amniotin Pessaries. These are vaginal suppositories containing amniotin in a glycerin and gelatin base to which is added 0.5 per cent of phenol as a preservative. Each suppository contains 2,000 international units. Fair absorption of the active

19 Adam N. K., Danielli J. F., Dodds E. C., Marrian G. F., Parkes A. S. and Rosenheim O. Nomenclature of the Oestrin Group. *Nature* 132: 205 (Aug. 5) 1933.

20 The ratios of international to rat unit employed by American firms are 1:3.33 (Parke Davis), 1:5 (Schering), 1:8 (Squibb). It is apparent that the rat units formerly employed by these firms were not equivalent. It is probable that the potencies as stated by the different firms in international units are more nearly comparable. However, E. Laqueur (Zur Eichung brunstgebender Stoffe. *Klin. Wchnschr.* 14: 739 [March 9] 1935) has pointed out that a comparison of two different estrogenic products on the basis of their claimed potency in international units is of little value unless the animal in which the comparison is made is stated. Rats for instance are much more sensitive to progynon B than to theelin (the international standard) while mice are equally sensitive to both. The comparative sensitiveness of the human being to the different products is unknown.

21 Conference on the Standardisation of Sex Hormones. London, July 30 and Aug. 1, 1932. League of Nations Quarterly Bulletin of the Health Organisation. Special Number on Biological Standardisation. January 1935.

22 The literature is reviewed by Sabotka Harry. *Chemistry of the Bile Acids and Related Substances*. Chem. Rev. 15: 311 (Dec.) 1934.

23 Oestroform and dimenformon apparently are not marketed in the United States.

24 Collip J. B., Browne J. S. L. and Thomson D. L. The Chemical Nature of Emmenin. *Endocrinology* 18: 71 (Jan. Feb.) 1934.

24a As the benzoate radical replaces one of the hydroxyl groups (which are directly involved in producing the estrogenic effect of this class of compounds) hydroxyestrin benzoate should not be considered simply a salt of the dihydroxy compound; it is a different estrogenic substance.

25 Allen Edgar. *The Physiology of Estrogenic Principles*. J. A. W. A. 104: 1498 (April 27) 1935. A more extensive discussion of these specific questions will be found in the Council report on Estrogenic Substances.

agent may apparently be obtained by the vaginal route, though this is of course less certain than by intramuscular administration

Amniotin Capsules Soluble gelatin capsules containing amniotin in corn oil, each capsule represents 1,000 international units, for oral administration

Emmenin, Ayerst, McKenna and Harrison This is an extract of placenta made by the method of Collip, apparently containing as its chief active principle a complex of theelin²⁴ not reduced to a crystalline state. Small quantities of other active substances such as theelin and theelol are probably also present. Emmenin is standardized as follows: One "day-oral unit" is the minimum amount administered daily in the drinking water which will produce a vaginal estrous reaction within 100 hours in 50 per cent of a group of rats from 18 to 21 days of age and weighing between 20 and 30 Gm. This preparation is marketed in the form of Emmenin Liquid for oral administration, each cubic centimeter containing 5 day-oral units (no data are available as to the relationship of this unit to the international unit). The recommended dosage varies from 4 to 30 cc per day. This product has been less extensively employed than some of the others.

Folliculin Menformon, Organon Laboratories, Amsterdam, Degewop, Berlin, H. H. Beisner, New York This product is said to contain theelin (estrone) as its active principle, though apparently it is not reduced to crystalline form during manufacture. The source is the urine of pregnancy. Dosage forms: Aqueous solution in 5 cc rubber-diaphragm-capped vials containing 1,000 international units in each cubic centimeter.

Oil solution (type of oil not specified) in 5 cc ampules containing 10,000, 50,000 or 100,000 international units in each cubic centimeter.

Tablets for oral administration containing 100 or 1,000 international units each.

Progynon²⁶ Schering Corporation This preparation is prepared from placenta and/or the urine of pregnancy. It is not purified in the process of manufacture, hence the exact nature of the active principle or principles is not known.

Dosage forms Ampules of 1 cc aqueous solution containing 125 international units.

Tablets containing either 225, 1,000 or 3,000 international units.

Progynon-B, Schering Corporation This is crystalline hydroxyestrin benzoate obtained by hydrogenation of theelin and subsequent conversion to the benzoate. The claim made by the Schering Corporation that progynon-B is the "real female sex hormone" is quite unfounded^{26a}. This claim is based on the recent report by MacCorquodale, Thayer and Doisy²⁷ of the isolation of a crystalline estrogenic compound from the liquor folliculi of hog ovaries. This compound was found to have a melting point within 1 degree C of and a biologic activity approximately equal to that of 3,17-dihydroxy 1, 3, 5 estratriene (not the benzoate). This does not constitute identification from the chemical standpoint, certainly there is no evidence that the compound obtained by MacCorquodale and his associates is the benzoate, nor is there evidence that the benzoate occurs naturally. In addition the newly isolated substance was obtained from hog ovaries, not only may there be other active substances in hog liquor folliculi but there is no available evidence whatever as to the nature of the estrogenic principle or principles in human ovaries. The claim of the Schering Corporation that progynon-B is "produced synthetically" may be misleading, the chemical processes whereby naturally occurring theelin is reduced and the benzoate formed

does not constitute "synthesis" as this term is commonly understood. The wording of the firm's recent advertising which implies that pyrogen-B is "six times as active" as the substance from which it is derived may also be misleading. While the claimed greater activity may be true under certain conditions with the dihydroxy form itself,²⁸ the benzoate (progynon-B) is said to be less active than the dihydroxy form.²⁹ Regardless of the relative potency in test animals, no information is available as to the comparative activity in human beings.²⁰

Progynon-B is marketed in ampules containing 1 cc. of a sesame oil solution of hydroxyestrin benzoate of either 2,500, 10,000 or 50,000 international units.

Theelin, Parke, Davis & Co. This is the crystalline keto-hydroxyestrin first isolated by Doisy and his associates. It is obtained from the urine of pregnancy. It is marketed in ampules containing 1 cc. of either the aqueous solution (167 international units) or the oily solution (type of oil not specified) (1,000 international units).

Theelol, Parke, Davis & Co. This is crystalline trihydroxyestrin, obtained from the urine of pregnancy. It is marketed in capsules for oral administration, each containing 50 Doisy rat units (according to the ratio employed by the firm, which is identical to that suggested by the Committee of the League of Nations, this would represent 167 international units).

A number of other preparations purporting to contain active estrogenic material are marketed in this country, however, insufficient information is available regarding these products to estimate their probable usefulness. Hence they will not be discussed here.³⁰ A large variety of estrogenic products are marketed in other countries.³¹ Commercial preparations made from the ovary³² generally contain little if any estrogenic material. Desiccated ovarian preparations were omitted from New and Nonofficial Remedies by the Council on Pharmacy and Chemistry in 1930.¹

CORPUS LUTEUM

The physiology of the corpus luteum has been discussed at length in the article in this series by Corner.³³ Since this article was written, the structure of the progestational hormone of the corpus luteum (designated "progestin" by Allen and Corner) has been elucidated.³⁴ The proposed formula, which illustrates the close relationship to the estrogenic compounds discussed in the previous section, is given in figure 4 (Allen, Butenandt, Corner and Slotta have adopted the name "progesterone" for the crystalline principle).

Comparatively little clinical application of active corpus luteum preparations has yet been made,³⁵ owing

²⁸ Reports in the literature with respect to the relative estrogenic activity of dihydroxyestrin (estradiol) and keto-hydroxyestrin (theelin estrone) vary within a wide range. Thus the dihydroxyl compound has been claimed to be from two to eight times as potent as theelin depending on the species of animal used and the method of assay. Laqueur²⁰ found that hydroxyestrin benzoate (progynon-B) was about five times as potent as theelin in rats but that the two compounds were about equally effective in mice.

²⁹ The benzoate, although it is less active, is employed because of its greater solubility.

³⁰ This group includes such products as estrogenic hormone (Reed and Carnrick), plestrin (Harrower), sistomensin (Ciba) and thelestrin (G. W. Carnrick).

³¹ Among European preparations said to contain estrogenic substance are dimenformon and folliculin menformon (both mentioned in the text), folipex (Sanabo-Chlnoin), fontanon feminin (Sachses Serum Werk), glandubolin (Richter), gynoestril (Laboratoire Française de Chimiotherapie), hormofollin (Labopharma), oestroform (mentioned in the text) and perlatan (Boehringer). This is not a complete list.

³² A number of these products are marketed with extravagant claims under fanciful names which serve in a measure to conceal their real identity.

³⁵ Bishop, P. M. F. Cook, Frank and Hampson, A. C. Indications for the Clinical Use of Progesterone. Lancet 1: 139 (Jan. 19) 1935. Krohn, Leon, Falls, F. H. and Lackner, J. E. On the Use of the Lutein Hormone Progesterone in Threatened and Habitual Abortion. Am. J. Obst. & Gynec. 29: 198 (Feb.) 1935.

²⁶ Progynon should not be confused with progynon-B. It is unfortunate that in this case, as in others, firms do not follow the Council's rule which forbids the use of letters or numbers as an integral part of a name. The confusion entailed by the use of letters is well illustrated in this instance.

^{26a} Progynon-B and the Ovarian Follicular Hormone. Report of the Council on Pharmacy and Chemistry. J. A. M. A. this issue, p. 676.

²⁷ MacCorquodale, D. W., Thayer, S. A. and Doisy, E. A. The Ovarian Follicular Hormone. Proc. Soc. Biol. Chem. April 10-13 1935, p. 1viii. The Crystalline Ovarian Follicular Hormone, Proc. Soc. Exper. Biol. & Med. 32: 1182 (April) 1935.

no doubt to the fact that until very recently satisfactory commercial products were not available³⁶

Proluton, Schering Corporation The method of preparation and assay of this product is not stated by the firm. The product is marketed in ampules (size unstated) containing $\frac{1}{2}$ or $\frac{1}{4}$ "European rabbit unit." This unit the firm claims to be "about 3 times stronger" than the American unit. If this unit represents the Claiberg unit, which seems probable, it appears according to Corner,³⁷ to be somewhat less than the rabbit unit as defined by Allen and Corner, and not three times greater as indicated by the firm.

Another preparation, **corlutin, Reed and Carnrick**, is said to be available but descriptive information on this product is lacking.

There is no evidence that any of the many products of corpus luteum intended for oral administration are of any therapeutic value. Solutions in ampules intended for parenteral injection, unless they are assayed for their content of progesterin, are probably equally valueless.

TESTIS HORMONE

No active preparation of the testis hormone or hormones appears to be available on the American market. Some products are manufactured by European firms, however, little adequate information is available as to

the activity of these products or as to their therapeutic applications. The formula of a compound isolated from urine by Butenandt and designated "androsterone," is given in figure 5³². Recent evidence indicates that this is not identical with the principle in extracts of the testis itself.

Among the European preparations purporting to contain testis hormone are **androl, Henning** (1 cc = 3 bird units), **androfort, Richter** (1 cc = 2 bird units), **hombreol, Organon Laboratories** (1 cc = 4 or 20 bird units)³⁷.

Preparations intended for oral administration as well as injectible solutions not assayed for their content of active principle are probably completely useless.

The theory proposed by McCullagh and his associates³⁸ that a principle exists in the testis (which they designate by the unfortunate term "inhibin") that may cause diminution in size of the hypertrophied prostate through depression of the pituitary is not based on adequate evidence. No adequately controlled studies appear to have been made on this hypothetical principle nor in fact has its existence been demonstrated.

36 Among European corpus luteum preparations said to contain progesterin are **glanducorpin (Richter)**, **luteogan (Henning)**, **luteolipex (Sanabo Chinoim)**, **lutex (Leo)**, **lutren (Bayer)**, **progesterin (British Drug Houses)**, **progesterin (Degewop)** and **progesterin (Organon Laboratories)**. This list is probably not complete.

37 Hombreol (and probably the others also) is made from urine and not from testicular tissue.

THYROID

Thyroid requires little discussion here, as the most commonly used product, desiccated thyroid, is described in the U S Pharmacopeia. Deviations from pharmacopeial potency of some of the commercial products are discussed in the article by Means³⁹. Reference is made also to the comprehensive article by Thompson and his associates,⁴⁰ in which the comparative effects of thyroxine and related compounds are considered at length.

PARATHYROID

Three commercial preparations containing the active principle of the parathyroid glands^{40a} are available, made according to the method of Hanson (for methods of preparation and assay see *New and Nonofficial Remedies*, 1935) **Parathyroid Extract-Lilly, N N R**, **parathyroid Extract-Squibb, N N R**, and **Paroidin, N N R-Parke, Davis & Co**. All are marketed in 5 cc rubber-diaphragm-capped vials containing 100 units in each cubic centimeter.

ADRENAL

Adrenal Medulla—The active agent of the adrenal medulla, epinephrine, is included in the U S Pharmacopeia. Commercial preparations of this substance are so well known as to require no description here (see *New and Nonofficial Remedies*, 1935).

Adrenal Cortex—Much confusion exists in this field with regard to nomenclature, methods of preparation of active extracts, methods of assay, the number of active principles in the gland, the potency of commercial products and the therapeutic indications for these products.

One of the commonly used names for extracts of the adrenal cortex is "cortin", this is the term originally applied by Hartman⁴¹ to a product made by salt precipitation, preparations made by this method were later shown to be practically or entirely inactive.⁴² The name was subsequently applied by Hartman to a product made by a different method employing lipid solvents, this process was the subject of a patent ("Cortin and Method of Preparing Same")⁴³. Thus the term is employed to represent two different products, if "cortin" is employed at all it should be restricted to extracts made by these methods specifically. The name is objectionable, however from several standpoints. It is derived from "cortex" and hence may represent the cortex of any organ, such as kidney or cerebrum (thus applies to "eschatin" also, as this is derived from the Greek for cortex). "Adrenocortin" is a more satisfactory term, but this is already preempted by a commercial firm (Harrower). "Cortin" is also employed by a German (Degewop) and a Dutch firm (Organon Laboratories) for their commercial extracts of adrenal

40a The physiologic and therapeutic effects of parathyroid are considered in two papers of this series. Hanson, A. M. *Physiology of the Parathyroid*. *J A M A* 106:113 (July 6) 1935. Aub, J. C. *Parathyroid Hormone Therapy*. *ibid* 105:197 (July 13) 1935.

41 Hartman, F. A., MacArthur, C. G. and Hartman, W. E. *A Substance Which Prolongs the Life of Adrenalectomized Animals*. *Proc Soc Exper Biol & Med* 25:69 (Oct.) 1927.

42 Stewart, G. N. and Rogoff, J. M. *Studies on Adrenal Insufficiency IX. The Influence of Extracts of Adrenal Cortex (Sheep and Cattle) on the Survival Period of Adrenalectomized Dogs and Cats*. *Am J Physiol* 91:254 (Dec.) 1929.

43 Hartman, F. A. *U S Patent 1914125* June 13 1933. Britton and Silvette (*Science* 73:322 [March 20] 1931) cast doubt also on the potency of extracts made by the lipid solvent method used by Hartman.

cortex. Thus the generic use of this term for any and all extracts of adrenal cortex leads to endless confusion, it should therefore be avoided.

Of the names employed to represent the life-sustaining principle of the adrenal cortex, the only one that is not objectionable from the standpoint of etymology is "interrenalin," proposed by Rogoff and Stewart,⁴⁴ who were the first to demonstrate the existence of this active principle in the gland.⁴⁵ Interrenalin is derived from "interrenal" gland, which is widely used among investigators as an inclusive designation for the gland represented in mammals by the adrenal cortex, in some species the interrenal gland forms an organ entirely separate from the chromaffin tissue (the adrenal medulla in mammals).

For the present, the Council on Pharmacy and Chemistry has adopted the generic term "adrenal cortex extract", however, no extract of this type stands accepted by the Council.

Practically all adrenal cortical extracts as now prepared contain toxic contaminants⁴⁶ (choline histamine, protein)^{46a} which have been reported to cause serious reactions both in man⁴⁶ and in animals⁴⁶ on parenteral injection. For this reason the extracts prepared by Rogoff and Stewart^{3a} were administered by mouth, by which route they were shown to be active (it is at present impossible to determine the relative activity by mouth and by parenteral injection in the human being). More recently Grollman and his collaborators⁴⁷ have proposed the oral use of adrenal cortical extracts. It appears, however, that none of the commercial preparations on the American market contain much, if any of the life-sustaining principle (the question as to whether more than one active principle exists is at present controversial, the evidence is conflicting and confusing). Only one satisfactory method of assay for the active principle exists, that is, the definite prolongation of life beyond the maximum survival time of untreated completely adrenalectomized animals. When subjected to this test, eschatin (Parke, Davis & Co.) made by the method of Swingle and Pfiffner, for instance, was found by Rogoff⁴⁶ to be not only not potent but toxic as well. The effects of extracts on blood urea, on the rate of production of muscular fatigue, or on the rate of growth of adrenalectomized animals (some of the methods employed at present) appear to be unsatisfactory as tests of potency. Consequently, the only reliable method for determining potency is largely qualitative and is difficult of standardization on a quantitative basis.

Further sources of error arise out of the use of commercial adrenal cortical extracts in patients errone-

ously diagnosed as having Addison's disease, most, if not all the so-called cures belong in this group. Still others occur through attributing improvement resulting from spontaneous remission in actual cases of Addison's disease as being due to the extract employed. Further discussion of this problem will be found in the paper in this series by Loeb.⁴⁸

One extract the potency of which appears to have been demonstrated indubitably both in adrenalectomized animals and in patients with Addison's disease is that of Rogoff.⁴⁸ This extract is not available commercially. Other potent extracts appear to have been prepared by investigators, but it seems that the difficulties of production on a commercial scale have not been surmounted.

PANCREAS

Insulin is discussed at length in two papers⁴⁹ of this series and need not be considered here. The products are described in New and Nonofficial Remedies. Pancreatin is considered in the article by Ivy,^{49a} this preparation is described in the U. S. Pharmacopeia. Other extracts of the pancreas will be discussed in a later section of this paper.

LIVER AND STOMACH PREPARATIONS

The actions and uses of liver and stomach preparations have been considered at length in the paper by West.⁴⁷ The following products (with two exceptions) stand accepted by the Council. (In view of the absence of satisfactory standards of antianemic potency for these products, no estimate of the relative potency will be made. It is expected that adequate standards will be established in the near future.)

Solutions for Oral Administration

Chappel Liver Extract (Oral), N. N. R., Chappel Bros., Inc.
Concentrated Liver Extract-Armour, N. N. R., Armour & Co.
Solution Liver Extract (Lederle) for Oral Use, N. N. R., Lederle Laboratories, Inc.
Solution Liver Extract, Valentine, The Valentine Company, Inc.

Powders for Oral Administration

Liver

Liver Extract-Fairchild, N. N. R., Fairchild Brothers & Foster
Liver Extract-Lederle, N. N. R., Lederle Laboratories, Inc.
Liver Extract-Illy, N. N. R., Elh Lilly & Co.
Liver Extract-Parke, Davis & Co., N. N. R.
Liver Meal, N. N. R., Livermeal Corporation

Stomach

Soluble Stomach Extract-Fairchild, N. N. R., Fairchild Brothers & Foster
Ventriculin, N. N. R., Parke, Davis & Co.

Stomach and Liver

Extralin, N. N. R., Elh Lilly & Co.

Solutions for Parenteral Administration

Chappel Liver Extract (Subcutaneous), N. N. R., Chappel Brothers, Inc.

Lederle Solution Liver Extract Parenteral Refined and Concentrated, N N R, Lederle Laboratories, Inc (This firm also markets a preparation approximately three times as concentrated as the one in N N R)

Liver Extract (Intramuscular)-Parke, Davis & Co, N N R
Solution Liver Extract Concentrated-Lilly, N N R
Solution Liver Extract-Lilly, N N R, Eli Lilly & Co

Other firms market liver extracts which are presumably potent, however, the foregoing products are sufficiently numerous to provide a wide choice, as they have met the Council's requirements as to antianemic potency they are to be preferred

YELLOW BONE MARROW

Extracts of yellow bone marrow⁵⁰ have been proposed for use in the treatment of granulocytopenia. The number of cases in which they have been employed is too few to serve as a basis for evaluation of this remedy. Much more clinical investigation will be necessary.

Yellow Bone Marrow Concentrate, Armour & Co. This is a solution in oil (nature not stated) of an extract of yellow bone marrow from tibias and femurs of cattle obtained by alkaline hydrolysis and extraction with certain solvents (nature not stated). Each drop is said to represent 2 Gm of fresh marrow fat. The average dose recommended by the manufacturer is 5 drops three times a day. More or less may be required, the dosage has not been adequately worked out. Frequent blood counts should be made during treatment.

THYMUS

While the preparation of active extracts of thymus has been reported by investigators,⁵¹ no commercial preparations appear to be available in this country that contain the active principle or principles. There are as yet no clinical indications even for the active preparations.

Combinations of thymus with extracts of other organs such as posterior pituitary have no scientific basis.⁵²

PINEAL BODY

Recent work on the pineal body indicates that this organ may have an endocrine function. A variety of effects have been observed following the injection of pineal extracts or implantation of pineal tissue into test animals.⁵³ Antiestrogenic, estrogenic, antigonadotropic and growth inhibiting effects have been reported by various investigators. It is too early to speculate as to the significance of these results. Although Burger⁵⁴ has reported that he has used a pineal extract in the treatment of certain cases of menorrhagia with good results, no data are presented. Much more needs to be known about the physiologic effects of such extracts.

before they are used therapeutically. There appear to be no active extracts of the pineal body available commercially in this country.

DEPRESSOR PRINCIPLES

A number of preparations claimed to cause vasodilatation have been proposed for use in the treatment of hypertension, angina pectoris, intermittent claudication and the like. The nature of the active principles involved, the site of action and the degree of therapeutic benefit occurring clinically are all controversial at present. The literature has grown to such proportions since 1926, when Frey and Kraut⁵⁴ announced the extraction from urine of a depressor principle ("kallikrein"), that it cannot be reviewed here. The substance occurring in urine was thought to be identical with a principle obtained from pancreas⁵⁵ and designated by the same name.

Among the extracts employed are products made from urine,⁵⁶ pancreas,⁵⁵ liver,⁵⁷ striated muscle⁵⁸ and kidney.⁵⁹ Some of the preparations are available commercially for either oral or parenteral administration. Although promising results have been claimed with a few of them, much more experimental work is required before their true status may be evaluated. The pertinent literature is reviewed by Wolffe, Findlay and Dessen.⁶⁰ These investigators employed an insulin-free pancreatic extract in the treatment of angina pectoris, with partial or complete relief of pain in the majority of their twenty cases. This extract produced cardiac slowing and a fall in blood pressure in experimental animals, it antagonized the pressor effect of epinephrine. With regard to the clinical use of insulin-free pancreatic extracts and muscle extracts in intermittent claudication, reference is made to the recent article by Barker, Brown and Roth.⁶¹ The latter are of the opinion that the preparations employed by them produce their therapeutic effect in this condition primarily by supplying some agent which facilitates muscular contraction and not by causing vasodilatation.

The liver extract ("eutonon") proposed for use in the treatment of angina pectoris by Zuelzer,⁵⁷ has been found to contain tyramine and choline as its active principles.⁶²

Encouraging results with kidney extracts in the treatment of hypertension were recently reported by Jablons,⁵⁹ but confirmatory work has not yet appeared. No commercial preparation of Jablons' extract appears to be available.

Until more is known with regard to the nature and physiologic effects of the various commercial extracts,⁶³ they should be employed for experimental purposes only

COMMENT

It is apparent from the foregoing discussion that clinical applications of many of the newer commercial glandular products are on a very unsatisfactory basis. Physicians, particularly those who do not have facilities for controlled clinical observation, would do well to be guided by the judgment of the Council on Pharmacy and Chemistry in the use of these products. The advertising propaganda of pharmaceutical manufacturers cannot be depended on as a safe guide in this respect

Council on Pharmacy and Chemistry

REPORTS OF THE COUNCIL

THE COUNCIL HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORT
PAUL NICHOLAS LEECH, Secretary

PROGYNON-B AND THE OVARIAN FOLLICULAR HORMONE

Recently MacCorquodale, Thayer and Doisy¹ of St. Louis University reported the isolation in crystalline form of an estrogenic substance from the follicular fluid of hog ovaries. Estrogenic compounds previously isolated such as theelin and theelol, had been obtained from other sources, in particular the urine of pregnant women. A pure estrogenic preparation had not before been isolated from the ovary itself. Consequently, the actual constitution of the ovarian follicular hormone or hormones was not known.

MacCorquodale, Thayer and Doisy reported that the crystalline product obtained by them from follicular fluid had approximately the same estrogenic potency as dihydroxyestrin (theelin is keto-dihydroxyestrin and theelol is trihydroxyestrin), that is, from four to eight times the activity of theelin. These investigators said in their preliminary report^{1b}

Although we have not yet accumulated sufficient material for complete analysis our results indicate the identity of the hormone with dihydro-theelin [more accurately designated dihydroxyestrin]. The m-bromobenzoate of the hormone was prepared and after three crystallizations had a melting point of 154-155°. After four crystallizations the m-bromobenzoate prepared from a sample of pure dihydro-theelin melted at 155°-156° and the dihydro-theelin obtained from it by saponification with dilute alcoholic alkali melted at 171°-172° after one crystallization. By saponification of the m-bromobenzoate of the hormone in the same manner the crystalline hormone was recovered and found to melt at 170-171°.

It appears then that the only evidence at present available for considering the crystalline preparation from ovarian follicular fluid to be identical with dihydroxyestrin is the similarity of the estrogenic activity and of the melting points. This, of course, does not constitute proof from a chemical standpoint of the identity of the two preparations.

Despite the paucity of the evidence at present available, the Schering Corporation has made claims in its recent advertising literature that Progynon-B (said to be the benzoate of dihydroxyestrin, which the firm calls "benzoic acid ester of dihydro follicular hormone") is the 'true female sex hormone, as was definitely proved by Doisy.

In an advertisement in the June 1935 issue of the *American Journal of Obstetrics and Gynecology* appears the following

'SCHERING DIHYDRO
FOLLICULAR SUBSTANCE
Conceded to be Real Sex Hormone
PRODUCED SYNTHETICALLY

Six Times as Active as Commonly Known Follicular Substance

That the true female sex hormone is not the follicular sex hormone that has been marketed under various names, as has been generally supposed but that it is rather the dihydro form of this substance has now been definitely established as scientific fact.

This discovery comes as a result of the work of MacCorquodale, Thayer and Doisy of the St. Louis University School of Medicine and was announced at the meeting of the American Society of Biological Chemists in Detroit April 10-13.

Three years ago Schwenk and Hildebrandt prepared by reduction of the follicular sex hormone the aforementioned dihydro follicular substance proved to be six times as active. These workers then ventured the opinion that this compound would prove to be the actual sex hormone which circulates in the body. Consequently the keto form of follicular substance would only be found to be the excretion form of the hormone. Later Wintersteiner, Schwenk and Whitman found the dihydro material in natural substances.

PROGYNON-B The Real Female Sex Hormone.

The dihydro follicular hormone which is the true female sex hormone has been produced synthetically by the laboratories of Schering Corporation in Bloomfield N. J. for over a year under the name of Progynon-B.

Clinical use has shown that the results from the use of Progynon-B are far more satisfactory than can be secured with the ordinary so-called follicular hormones which are merely the excretion form of the true hormone. For amenorrhea, dysmenorrhea, menopausal disorders and other deficiencies of the female sex cycle.

Inquiry was made of Dr. Doisy as to the status of the preparations concerned. Dr. Doisy replied in part:

"In our latest paper presented before the American Society of Biological Chemists we gave data to substantiate our claim of the isolation of the crystalline hormone contained in the liquor folliculi from hog ovaries. Actually, our results do not exclude the possibility of the presence of other active estrogenic compounds in hog liquor folliculi.

Furthermore there is no definite evidence regarding the nature of the estrogenic substances of human ovaries. Reasoning by analogy is certainly fallacious as is evidenced by the nature of the estrogenic substances in human urine—theelin and theelol—in both the combined and free forms and in the urine of pregnant mares—theelin, dihydrotheelin (an isomer of the compound which we have obtained from hog liquor folliculi), equiline, equilenine and hippuline. We believe that the available evidence indicates that the active substance of hog liquor folliculi is present in an unconjugated form. So far as I know, there is no reason for believing that the conjugated form is the one secreted by the ovary. Furthermore, I know of no evidence that the conjugated forms appearing in the urine of pregnancy are benzoates.

'The Schering claim of greater activity seems to be sound but has little significance. However, I must point out that the estimate of greater activity is limited to the production of cornification in the vagina. We do not know that the dihydro compound produces a greater effect on the uterus or mammary glands of experimental animals and there is no information that the dihydro compound is more active in the treatment of the human.

"The claim of a synthetic compound is certainly not warranted, since the dihydro compound is prepared from the keto-dihydroxy compound by reduction of the carbonyl group. In other words the chemist starts with the conjugated ring structure containing all the substituents in the correct position. Such a reaction does not correspond to the usual conception of synthesis.

The advertising claims of the Schering Corporation for Progynon-B are therefore inaccurate and misleading.² The Council voted that this report be published to correct the erroneous impressions created by the reprehensible advertising policy of this firm.

63 Among the available commercial extracts are: 1. Insulin-free pancreatic extracts: angiochol (Laboratoire des Proxystases Paris), padutin (Bayer), pancreatic tissue extract number 568 (Sharp and Dohme). 2. Skeletal muscle extracts: myofort (Richter), myorgal (Winthrop) (known in Europe as lacarnol), myoston (Henning), MAP (Henning) (muscle adenosine phosphoric acid). 3. Liver extract: eutonon (Promonta).

1 (a) MacCorquodale, D. W., Thayer, S. A. and Doisy, E. A. The Ovarian Follicular Hormone. *Proc. Soc. Biol. Chem.* April 10, 1935, p. 1711. (b) The Crystalline Ovarian Follicular Hormone. *Proc. Soc. Exper. Biol. & Med.* 32: 1182 (April) 1935.

2 This report is not concerned with the overoptimistic claims as to the indications for and the therapeutic effectiveness of Progynon-B or other estrogenic preparations. In this respect the advertising claims of other firms for other estrogenic products are also open to severe censure. For a critical evaluation of the therapeutic usefulness of these preparations reference is made to the Council's report, *Estrogenic Substances: Theelin* (J. A. M. A. 100: 1331 [April 29] 1933) and to Dr. Novak's article in the *Series of Glandular Physiology and Therapy* (The Therapeutic Use of Estrogenic Substances) J. A. M. A. 104: 1815 [May 18] 1935.

MEDICAL EDUCATION IN THE UNITED STATES AND CANADA

ANNUAL PRESENTATION OF EDUCATIONAL DATA FOR THE ACADEMIC YEAR
1934-1935 BY THE COUNCIL ON MEDICAL EDUCATION AND HOSPITALS

This report for the academic year 1934-1935 includes either statistical data or editorial comment regarding the medical schools approved¹ by the Council on Medical Education and Hospitals during this period. Also included are revised lists of hospitals approved for internships and residencies in specialties and the Essentials of an Acceptable School of Occupational Therapy.

Figures are presented covering seventy-seven medical schools in the United States and ten in Canada, 697 hospitals approved for internships and 392 hospitals offering approved residencies in specialties.

These data are based on official reports from the institutions listed. Acknowledgment is tendered the officers of these institutions for their ready cooperation in supplying the facts included in this presentation as well as for other material furnished throughout the year enabling the Council to maintain its medical student and hospital registers efficiently.

RESURVEY OF MEDICAL EDUCATION

Forty-five institutions in the eastern part of the United States have been inspected during the past year in connection with the resurvey of medical education. Although the study is, of course, incomplete, certain conditions needing improvement have already been clearly revealed.

During the last ten years the number of medical students has greatly increased (table 10). A number of factors may have contributed to this result. The great increase in college enrolments since the war doubtless has created a much larger body of students who aspire to a professional career. In law schools a corresponding increase in the number of students has also been observed. In recent years, financial stringency has caused some medical schools to rely more largely on the income from student fees, and larger numbers of students have been accepted for the sake of gaining additional revenue. Unfortunately, in most instances the teaching staff has not been correspondingly strengthened or the physical plant commensurately enlarged. In consequence it has been found that too often faculties are undermanned and laboratories overcrowded. A more serious feature of increasing enrolments is the failure to maintain high academic standards in the selection of students. Too many applicants with poor scholastic records have been accepted, with inevitable impairment of the efficiency of the school.

When the Council first graded medical schools, nearly thirty years ago, the curriculum was sharply divided into two preclinical and two clinical years. More recently a transformation has been taking place by which clinical subjects are being pushed back into the first two years. So it comes about that institutions which, lacking clinical facilities, were approved as "two year schools" have been unable to keep pace with this development. Some readjustment, therefore, of the status of these institutions seems to be inevitable.

There has been noted a very uneven development of clinical facilities. Some schools own and operate

their own hospitals and dispensaries. Some have affiliations whereby the university has the privilege of nominating or selecting the medical staff, while some other agency is responsible for the financial support of the hospital or dispensary. Others operate under less satisfactory arrangements, the school being obliged, in order to obtain any teaching privileges at all, to accept as members of its faculty men who owe their positions to other organizations with other aims, and who would not have been selected on the basis of training and experience for high positions of academic responsibility.

The lack of adequate clinical material is most strikingly evident in the field of obstetrics, and consequently failure to provide sufficient practical experience under competent supervision is one of the most serious defects thus far recorded.

PREMEDICAL EDUCATION

Since 1918 one of the essentials of an acceptable medical school has been a premedical requirement of two years of college work including courses in physics, chemistry and biology.

In June 1933 the following statement from the By-Laws² of the Association of American Medical Colleges was adopted by the Council as its premedical standard. In substance it does not differ from the two-year college prerequisite. No attempt is made to outline courses to be pursued in secondary schools.

SEC. 2—Requirements for Admission. Admission to medical schools and medical colleges in membership in the association may be by

(1) Satisfactory completion of a minimum of collegiate instruction, as provided below in subsection I, or by

(2) Examination, as provided in subsection II.

Subsection I. The minimum of collegiate credit required for entrance to medical schools and colleges in membership in the association shall be not less than two full academic years, which shall include English, theoretical and practical courses in physics and biology³ and in general and organic chemistry, completed in institutions approved by accrediting agencies acceptable to the executive council of the association.

Exception may be made under this section in that any member may admit applicants who have fulfilled the requirement in American and Canadian institutions not approved by such accrediting agencies, provided that all admissions so made be reported to the executive council and shall be published in the next annual report of the council.

All collegiate instruction given in satisfaction of this requirement must be based on the same entrance requirements and must be of the same quality and standard of instruction as that required for a baccalaureate degree in the institution in which the candidate received his preparation.

Subsection II. Admission to medical schools and medical colleges in the association may be by examination.

Examinations for the purpose of admission by this method shall be conducted by institutions acceptable to the executive council of the association, under the following conditions:

(a) Candidates who have completed two years of collegiate instruction and present evidence of general scholarship of high

(Continued on page 682)

² Constitution and By-Laws of the Association of American Medical Colleges amended Oct. 30, 1934.

³ Exceptions may be made in these subject requirements only in unusual cases. Proposed exceptions shall be presented to and approved by the executive council.

¹ Including three schools whose approval has recently been withdrawn. See footnotes to table 1, page 679.

of Students

[illegible]

(Continued from page 677)

order but who lack credits in not more than two of the required subjects, may be admitted on passing examinations in these subjects

(b) Candidates who have completed three years of collegiate instruction and present evidence of having accomplished work of distinction in one or more fields of learning, but who lack credits in any or all of the required subjects, may be admitted on passing examinations in these subjects

Forty medical schools in the United States have adopted requirements in excess of this minimum, 1 e four require a degree, thirty-two require three years, one requires four years, and three admit students with three years of college work if the baccalaureate degree is conferred in absentia at the end of the first year in medicine. The medical schools of Canada vary with regard to the premedical requirement. One requires a degree, three have a two year requirement, one requires one year, one requires three years, and four schools have a six year medical course including premedical subjects

For the guidance of prospective medical students and admitting officers, the Council publishes annually a compilation of college of arts and sciences approved by the following agencies

Association of American Universities
Middle States Association of Colleges and Secondary Schools
New England Association of Colleges and Secondary Schools
North Central Association of Colleges and Secondary Schools
Northwest Association of Secondary and Higher Schools
Southern Association of Colleges and Secondary Schools

The Association of American Medical Colleges endorses the lists of evaluating agencies included in the Council's publication but in addition recognizes also the colleges approved by a state university

College grades serve as a basis for selection in almost all medical schools. Candidates with an average grade of C or lower are regarded as poor risks. The medical aptitude test conducted by the Association of American Medical Colleges is another useful criterion in the appraisal of applicants. Many schools also require a personal interview

The preliminary requirement of each school will be found in table 1. No attempt has been made to outline the admission requirements, since they vary considerably

The two year premedical requirement has been in effect since 1918—seventeen years. However, there are eight states which have not adopted this standard as a legal requirement for licensure. Six of these states will not admit to licensure other than graduates of recognized medical schools which enact this requisite. The statutes of these states should be amended to conform

LENGTH OF MEDICAL COURSE

The medical curriculum in the United States in general is taught in four years of thirty-two weeks each. The medical schools of the universities of Minnesota, Duke and Tennessee operate on the quarter plan, permitting the student by utilizing the summer months to complete the course in three calendar years. The two medical schools of the University of Chicago operate on the individualized plan of instruction whereby a student progresses as rapidly as his ability permits. Fourteen medical schools in the United States require a year of internship or research as a part of the medical course, thereby lengthening the course to five years

Duke University requires a two year internship. Ten schools offer only the work of the first two years

Five of the medical schools of Canada offer a five year course, four have a six year course including premedical subjects, and the University of Saskatchewan offers only the first two years of the medical course. These data are included in table 1. Three of the Canadian schools have an internship requirement

CURRICULUM

The Council recognizes as the standard curriculum that provided in the By-Laws² of the Association of American Medical Colleges, which is as follows

SEC. 3 Curriculum. The entire course of four years shall consist of from 3,600 to 4,400 hours, distributed as from 900 to 1,100 hours per year, and shall be grouped as set forth in the following schedule, each group to be allotted approximately the percentage of hours of the whole number of hours in the courses as stated

	Hours	Per Cent
1 Anatomy including embryology and histology	14	18.5
2 Physiology	4.5	6
3 Biochemistry	3.5	4.5
4 Pathology bacteriology and immunology	10	13
5 Pharmacology	4	5
6 Hygiene and sanitation	3	4
7 General medicine	20	26.5
Neurology and psychiatry		
Pediatrics		
Dermatology and syphilis		
8 General surgery	13	17.5
Orthopedic surgery		
Urology		
Ophthalmology		
Otolaryngology		
Röntgenology		
9 Obstetrics and gynecology	4	5
Total	76	100
Electives	24	0

When the teaching conditions demand it, a subject may be transferred from one division to another

STATISTICS OF MEDICAL SCHOOLS

Table 1, pages 678 and 679, lists the medical schools in the United States and Canada recognized by the Council on Medical Education and Hospitals of the American Medical Association during 1934-1935 and contains figures regarding the premedical requirement by years for the session 1935-1936, length of the medical course by years, enrolment by classes for the session 1934-1935, including fifth year students intern-ing or engaged in research, number of graduates since July 1, 1934, dates of the beginning and ending of the forthcoming session, and the month until which applications for admission to the freshman class are received. Changes in the classifications that have taken place since the publication of the educational statistics in 1934⁴ can be noted in the footnotes at the bottom of the table and refer to those schools which are marked by asterisks preceding the name. Also contained in the footnotes are references to the fifth and sixth year enrolments and those schools which admit students at varying times during the year

The data presented in this table constitute the basis also for several of the subsequent tabulations. Beginning on page 692 are given historical information and essential facts concerning the schools arranged by states

Seventy-seven institutions in the United States and ten in Canada are listed. With the exception of three, all these schools at the present time enjoy full approval by the Council. In eighty-four schools there were 6,989 freshman students enrolled, 6,200 sophomores, 5,698 juniors, 5,438 seniors, 373 fifth year and 220 sixth year students, during the session just ended. The students enrolled in the two medical schools of the Uni-

versity of Chicago and Duke University are not classified by years. In these three schools there were 861 students enrolled, making a total of 25,779 in the eighty-seven schools listed. In the United States alone there were 6,356 freshmen, 5,624 sophomores, 5,142 juniors and 4,905 seniors and the 861 students mentioned above, a total of 22,888. The enrolment in Canada was as follows: first year, 633, second year,

with 1,231. From the twelve states that do not have medical schools there were enrolled as students the following

Arizona	40	New Jersey	860
Delaware	45	New Mexico	32
Florida	119	Rhode Island	146
Idaho	74	Washington	257
Maine	115	Wyoming	22
Montana	85		
Nevada	22		1 817

There were ninety-seven born in the United States possessions and 885 in foreign countries. In addition 2,400 Canadians were also studying medicine, the majority enrolled in the medical schools of Canada.

In table 3 the medical school enrolment is further classified by birthplace indicating that 14,842 are studying in the state of their birth and 10,937 elsewhere. This is particularly significant in Illinois, where, of the 2,309 students in five schools, 1,116 were born outside the state. It may be that many of these have become residents of the state.

More than 800 born in New York are studying elsewhere. Altogether, 42 per cent are studying in schools located in states other than their birth. Eliminating the 1,817 born in states having no medical school, there are still 9,120 of the 25,779 studying outside their birth state.

A perusal of the table will show many instances in this classification wherein the number studying elsewhere far exceeds the number attending school in the

TABLE 3—Students Classified by Birthplace

State	Number of Schools	Attending School in State of Birth	Birthplace Elsewhere

Totals	67	14 842	10,937

576, third year, 556, fourth year, 533, fifth year, 373, and sixth year, 220, a total of 2,891. The 25,779 students enrolled do not include 1,347 students intern-ing as a requirement for the degree. Since July 1, 1934, 5,101 received M.D. degrees from schools in the United States and 457 from Canadian institutions. In addition there were enrolled 133 part-time, 244 special and 718 graduate students. Nine schools had an enrolment of less than 100, fifteen less than 200, twenty-three less than 300, seventeen less than 400, thirteen less than 500, eight less than 600, and two schools had an enrolment of more than 600. The smallest enrolment was at Dartmouth Medical School (thirty-nine), which offers only a two year course, the highest enrolment was at the University of Toronto Faculty of Medicine (816) which has a six year course including premedical subjects. The lowest enrolment among four year colleges was 112 at Albany Medical College and the highest 614 at the University of Illinois College of Medicine. Louisiana State University Medical Center had the lowest number of graduates (nineteen) and Rush Medical College had the highest (152).

BIRTHPLACE OF STUDENTS

Table 2, pages 680 and 681 shows the birthplace of students in attendance at each medical school during the past session. The state furnishing the greatest number of students was New York, 3,478, followed by Pennsylvania with 2,207, Illinois with 1,549 and Ohio

state of birth. It also shows some states in which the contrary is the case, notably Indiana, Iowa and South Carolina.

SCHOOLS, STUDENTS AND GRADUATES BY STATES

The number of schools, students and graduates for each state are given in table 4. New York, with the largest number of schools, nine, naturally had the largest number of students and graduates, 2,705 and 633 respectively. Pennsylvania with six schools had 2,429 students and 575 graduates. Illinois was third

with five schools, 2,309 students and 573 graduates. In four schools in California there were 1,039 students enrolled and 216 graduates, while in three schools in Massachusetts there were 1,260 students and 311 graduates. In the seventy-seven schools in the United States, including those that offer only the preclinical courses, there were 22,888 students and 5,101 graduates. Canada, with ten schools, had 2,891 students and 457 graduates.

REQUIRED INTERNSHIPS

In tables 5 and 6 are listed the state licensing boards and medical schools now requiring internships for licensure and the M D degree respectively. Some of these schools will accept research or other clinical work in lieu of the internship. There is also included the effective date of the requirement. Seventeen states, the District of Columbia and Alaska and fifteen schools in the United

* Requires a two year internship

States and three in Canada are mentioned in these tables. During 1934-1935 there were 1,233 students of the United States and 114 in Canada reported as interns, a total of 1,347. Duke University School of Medicine grants the degree after the completion of the senior year, but all graduates are required to spend at least two years in hospital or laboratory work after graduation. While some of the licensing boards may have their own list of hospitals recommended for intern training, generally the Council's list of hospitals approved for internships is followed. A revised edition will be found beginning on page 699.

GRADUATES AND INTERNSHIPS

Table 7 contains figures regarding graduates from July 1, 1933, to July 1, 1934, who have served or are serving internships during the period July 1, 1934, to July 1, 1935. The figures for the graduates differs from that mentioned elsewhere in these statistics, since those who received M D degrees in 1934 on completion of

a required internship that was served during July 1, 1933, to July 1, 1934, are omitted and also a few others. The second column, however, includes those serving internships as a requirement for the degree to show

all graduates here listed have this added experience. It is a known fact that there is a scarcity of internships and it may be that of the 6 per cent who have not been reported as interning many have found it difficult to secure internships in approved hospitals.

DISTRIBUTION BY SEX

Students and graduates classified by sex are shown in table 8. There were seventy-five schools which had both men and women students in the United States and Canada, of which fifty-eight had women graduates. Altogether there were 24,588 men and 1,191 women students, and 5,332 men and 226 women graduates. There is one medical college for women, the Woman's Medical College of Pennsylvania, which had 132 students and thirty-two graduates, leaving 1,059 women students pursuing their medical education and 194 who completed the course in coeducational institutions.

During the past year there were 1,077 women studying medicine in the United States, fifty-seven more than last year. The percentage of women to all medical students this year is 4.7 as compared with 4.5 in 1933. There were 207 graduates, four fewer than last year. Of all the women matriculants, 132 students were in attendance at the one medical college for women, the Woman's Medical College of Pennsylvania, while 945 were matriculated in sixty-seven coeducational schools. From the Woman's Medical College, thirty-two were graduated, while 175 secured their degrees from coedu-

TABLE 9.—Women in Medicine in the United States

Year	Women students	Percentage of All Students	Women Graduates	Percentage of All Graduates
1900	1,078	4.1	219	4.0

1935	1,077	4.7	207	4.1

cational institutions. As shown in table 9, the number of women students has been rather constant since 1920, although in 1935 there were more than in any other year.

MEDICAL SCHOOLS STUDENTS AND GRADUATES IN THE UNITED STATES 1905-1935

The number of medical schools, students and graduates in the United States for each five year period from 1905 to 1920, and for each year since, is shown in table 10. The total number of undergraduate medical students for the college session 1934-1935 was 22,888, an increase of eighty-nine over the previous session. This is the largest number of students enrolled since 1905, when 26,147 were in attendance at the 160 medical schools then existing. Also included are figures covering the number of students enrolled in schools offering only the preclinical courses. Not included in the total number of students for 1935 are 133 part time, 244 special and 718 graduate students majoring in the medical school but not working for M.D. degrees.

Again referring to table 10, it will be noted that the total number of graduates was 5,101, an increase of sixty-six over the preceding session. With the exception of the slight decrease in the number of graduates in 1933 as compared with previous years there has been a steady increase since 1926. As will be noted, there were marked increases in 1923, 1924 and 1925. While

there was a decrease in the number of graduates in 1933, there was an increase in the number of students

The number of students and graduates for each five year period since 1905 is shown graphically. In 1905

Number of medical students over thirty year period

there were 26,147 students. The next fifteen years shows a decrease and since a noticeable increase. The Council has issued a general warning against the admission of larger classes than can properly be accommo-

‡ Intern year

dated or than can reasonably be expected to satisfy approved scholastic standards. Seven schools have definitely stated that their enrolment will be decreased and others have indicated adherence to the Council's principles.

In this connection it is interesting to note the number enrolled in the various classes in the United States for

each session from 1930-1931 to 1934-1935 inclusive, as shown in table 11. The total attendance for the first year for the session 1934-1935 was 6,356, or 101 fewer than the number enrolled for the session 1933-1934. The figure, however, is 100 more than were enrolled during 1930-1931. The total attendance for the remainder of the classes was, respectively, 5,624, 5,142, 4,905 and 1,233. The two medical schools of the University of Chicago are not operated under the promotion by class system but on an individual plan. It is not possible, therefore, to group them into the figures given.

Total	87

* Based on fees charged resident students

This is likewise true of the enrolment at Duke University School of Medicine. They are, however, included in the totals. There were 210 students enrolled at Duke 339 at the School of Medicine of the Division of the Biological Sciences of the University of Chicago and 312 at Rush Medical College, a total of 861. There were 1,114 more students enrolled than in 1930-1931. Only one new medical school has opened since that session, namely, the Louisiana State University Medical Center, which had an enrolment of 301 for the session of 1934-1935. Excluding the students of this university, there were 813 more students enrolled during the past college session than in the seventy-six medical schools that existed in 1931.

The Association of American Medical Colleges⁶ reports that there were 32,321 applications for admission to the freshman class, representing 12,779 applicants, and of these 7,419 were accepted and 5,360 refused. However, as already indicated, only 6,356 actually enrolled for the freshman year, exclusive of the University of Chicago and Duke University enrol-

students and 104 graduates, a decrease of twenty-two students but an increase of four graduates over the figure for the previous year. Meharry Medical College was organized in 1876 as a medical college for Negro youth, and at Howard University College of Medicine, organized in 1869, they compose a majority of those in attendance. These two schools graduated

It is believed this figure should be larger inasmuch as the following schools previously reported large numbers of American students: Vienna, Austria; Bologna and Naples, Italy; St. Mungo's, Scotland; and Geneva, Switzerland.

ment. It may be noted that 700 students were accepted by medical schools who did not matriculate in a medical school in 1934-1935 principally because of multiple application.

NEGROES IN MEDICAL SCHOOLS

The Negro medical students for the session 1934-1935 are recorded by classes in table 12. The totals for 1933-1934 are shown for comparison. There were 402

the majority of the Negro students. All other schools enrolled less than seven.

TUITION FEES

In table 13, the eighty-seven medical colleges of the United States and Canada have been grouped according to the amount of fees charged. To arrive at the figures listed, an average was compiled of the fees for each school. Included in these fees are the various minor charges, such as for matriculation, breakage, diploma and graduation. Three colleges have fees of

less than \$100 a year. These were the Louisiana State University, North Dakota and Oklahoma. They, however, charge an additional fee of \$300, \$90 and \$200, respectively, for nonresidents. The ten colleges having fees over \$500 are Yale, Johns Hopkins, Columbia, Cornell, Long Island, New York Homeopathic, Syracuse, New York University, Buffalo and Pennsylvania. There were thirty-two universities which made an additional charge for nonresidents, ranging from \$50 by the Universities of Mississippi, Missouri, Cincinnati (nonresidents of Cincinnati), Tennessee and Virginia to \$300 exacted by the Universities of California and Louisiana State.

The lowest nonresident fee was charged by the University of Utah, \$35. No noticeable increase or decrease has been noted in the fees charged by medical schools. The fees are not listed in these statistics by

individual schools other than in the descriptions beginning on page 692. Provision is made also for scholarships and loan funds for deserving students.

CITIZENS OF THE UNITED STATES ENROLLED IN MEDICAL FACULTIES ABROAD

A study of the number of citizens of the United States enrolled in medical faculties abroad will be found in table 14. This tabulation covers the academic year 1934-1935. There were 1,471 students and 199 graduates or those who completed their medical training in the ninety-seven institutions reporting. This study has been carried on since 1931, when it became evident that great numbers of Americans were going to Europe to study. The files of the Association of American Medical Colleges shows that the application record of 502 students whose names were supplied this year indicates that 106 have made application to medical schools in the United States without success since 1931. There were as many as twenty-five rejections by medical

schools in individual cases, indicating their inability to obtain a medical education in this country. In view of the problem created by this migration, the Federation of State Medical Boards of the United States in February 1933 adopted a resolution to the effect that no student matriculating in a European medical school subsequent to the academic year of 1932-1933 will be admitted to any state medical licensing examination who does not present satisfactory evidence of premedical education equivalent to the requirements of the Association of American Medical Colleges and the Council on Medical Education and Hospitals, and graduation from a European medical school after four academic years of attendance, and further submits evidence of having satisfactorily passed the examination to obtain a license to practice medicine in the country in which the medical school from which he is graduated is located.

This policy of the federation has been made effective by individual action on the part of the state licensing bodies and the National Board of Medical Examiners and will have its desired effect in the future.

For the purpose of keeping closely in touch with developments in other countries, a joint committee was appointed representing the Council on Medical Education and Hospitals, the Federation of State Medical Boards of the United States, the New York Board of Regents, the National Board of Medical Examiners, and the Association of American Medical Colleges.

Further, in 1934 the Federation of State Medical Boards passed a resolution to the effect that the federation recommend to its constituent state boards and to the National Board of Medical Examiners that, until adequate information is available, these boards deny graduates of foreign medical schools admission to the various medical licensure examinations.

The governments of many European countries have already taken cognizance of the situation and sent representatives to this country to discuss appropriate measures for dealing with students from the United States. In some universities, entrance requirements have been raised, in some, student enrolment has been limited. In all cases, credentials will be carefully scrutinized.

The enrolment of these students in foreign faculties as reported to us for each session since 1930-1931 is shown in table 15. The largest numbers were enrolled in Austria, Germany, Italy, Scotland and Switzerland. Those enrolled in 1930-1931 (710), if still studying abroad, will probably finish their course during this year or next and it may be expected that most of them plan to return to the United States to practice.

GRADUATE MEDICAL EDUCATION

Table 16 contains information regarding opportunities for graduate medical education by universities in the United States and Canada elicited from an inquiry as to whether (1) definitely organized courses for graduates were being offered, (2) graduate training was being conducted in an informal way, i. e., by residencies, fellowships, etc., (3) students enrolled primarily in the graduate school are permitted to do part of their work under the direction of the medical faculty, and (4) the institution engages in extension teaching in the field of medicine. Twenty-nine schools report that they have organized courses and two universities have graduate schools of medicine. Fifty-three offer residencies or fellowships. Courses in the graduate school under the direction of the medical faculty are reported by

* Institutions offering graduate medical courses other than universities are not included in this tabulation
+ yes no reply 0 no

fifty-six schools and extension training by nineteen. Nineteen schools do not offer graduate work.

This table does not include institutions offering graduate medical courses other than universities, such as the New York Polyclinic and the New York Eye and Ear Infirmary. It therefore does not give a complete picture but will give the reader a fairly good idea of graduate instruction in the United States. The Universities of Southern California, Georgia, Iowa, Columbia, Pennsylvania and Western Ontario offer all four types of education.

NECROPSIES IN HOSPITALS APPROVED FOR INTERNSHIPS

While the performance of necropsies in hospitals is only one of many important functions, it is nevertheless a valuable index to the scientific interests of the staff.

TABLE 17—Approved Internship Hospitals with Highest Necropsy Percentages 1934

	Control	Deaths	Necropsies	Necropsy Percentage
1 Research and Educational Hospital Chicago	State	217	107	90.8

20 St Mary's Hospital Duluth Minn	Church	220	158	69.9

NP Assn nonprofit association Fed federal

and their efficiency in the training of interns. All of the 697 hospitals now approved for intern training met or exceeded the 15 per cent requirement. A few were removed during the year because of low necropsy rates and other deficiencies.

The names of twenty hospitals achieving the highest rate during the year 1934 are given in table 17. Of these, seven were operated by nonprofit associations, seven were state hospitals, four church hospitals, one federal and one county hospital. However, the total results were as follows:

1934 Necropsy Averages		
No of Hospitals	Control	Average Percentage
36 Federal and state		59.1
87 City and county		35.1
270 Church		27.9
273 Nonprofit associations		33.8
26 Profit associations		28.4
5 Fraternal individual industrial and partnership		29

The progress made between 1926 and 1934 is shown in the following figures:

Necropsy Rate		Number of Hospitals	
		1926	1934
15 per cent to 29 per cent		146	371
30 per cent to 49 per cent		68	239
50 per cent to 69 per cent		21	59
70 per cent and above		14	28

The rate of necropsy performance achieved by each of the 697 hospitals now approved for internship is given among other data in the revised list of approved hospitals beginning on page 699.

ESSENTIALS OF AN ACCEPTABLE SCHOOL OF OCCUPATIONAL THERAPY

I ORGANIZATION

1 A school of occupational therapy should be incorporated under the laws regulating associations which are operated not for profit. The control should be vested in a board of trustees rather than an individual. This board should be composed of public spirited men or women receiving no financial benefits from the operations of the schools. The trustees should serve for fairly long and overlapping terms. If the choice of trustees is vested in any other body than the board itself, this fact should be clearly stated. Officers and faculty of the school should be appointed by the board.

2 Affiliation with a college, university or medical school is highly desirable but is not an absolute requirement.

3 Schools of occupational therapy should not be operated by hospitals independently. It is understood, however, that hospitals are needed for practice training and especially for graduate training in the special branches of occupational therapy.

II FACULTY

1 The school should have a competent teaching staff graded and organized by departments. Appointments should be based on thorough education and training and successful teaching experience. Nominations for faculty positions should be made in accordance with academic custom. The staff should include not less than one regular salaried instructor and one registered occupational therapist. The question of full time and part time appointments is not as important as the qualifications of the instructors, who should be specialists or exceptionally well trained and well qualified in the lines they are teaching.

III PLANT

1 The school should own or enjoy the use of, buildings sufficient in size to provide adequate lecture rooms, class laboratories and administration offices. Equipment should be adequate for teaching and training. Anatomic charts, manikins and dummies should also be provided. There should be a library receiving regularly all the leading periodicals pertaining to occupational therapy, current numbers of which should be easily accessible to the students.

IV ADMINISTRATION

1 *Supervision*—There should be careful and intelligent supervision of the entire school by the dean, director or other executive officer, who, by training and experience, is fitted to interpret the prevailing standards and who is clothed with sufficient authority to carry them into effect.

2 *Records*—There should be a good system of records showing conveniently and in detail the credentials, attendance, grades and accounts of the students by means of which an exact knowledge can be obtained regarding each student's work. Schools should require that students be in actual attendance within the first week of each annual session and thereafter. Except for good cause, no credit should be given for any course when attendance has been less than 80 per cent.

3 *Credentials*—The admission of students to the occupational therapy school must be in the hands of a responsible committee or examiner, whose records shall always be open for inspection. Documentary evidence of the student's preliminary education should be obtained and kept on file. When the occupational therapy school is an integral part of the university, this work usually devolves on the examiner or registrar.

4 *Advanced Standing*—At the discretion of the administration, advanced standing may be granted for work required in the occupational therapy curriculum which has been done in other accredited institutions. Official verification of previous work should be obtained by direct correspondence. Preliminary qualifications should also be verified and recorded.

5 *Number of Students*—The number of students admitted to the training course should not be excessive. In practical work of a laboratory nature the number of students that can be adequately supervised by a single instructor is in general experience, about fifteen, in lectures the number may be much larger. A close personal contact between students and members of the teaching staff is essential.

6 *Discipline*—All training schools reserve the right to drop a student at any time for any cause which the school authorities deem sufficient

7 *Publications*—The school should issue, at least biennially, a bulletin setting forth the character of the work which it offers. Such an announcement should contain a list of the members of the faculty with their respective qualifications

V PREREQUISITES FOR ADMISSION

Requirements for admission shall be

1 *Age*—The admission of candidates should be governed by the fact that it is required that each student be not less than 21 years old at graduation

2 *Education*—All candidates must furnish proof of having completed a high school education or its equivalent. In addition, it is desirable that all candidates, except those for the degree course, shall have had at least one year and preferably two years, of further education or successful experience in college art school, social service, nurse's training or the commercial field

Candidates for admission to a training course in a college or university which is combined with work leading to a bachelor's degree should be required to comply with the regular entrance requirements of the institution concerned.

3 *Character*—All candidates should be required to present evidence of good character and general fitness, the evidence of which should be investigated and duly weighed by the school concerned

4 *Health*—All students should be given a physical examination under the supervision of the school as soon as practicable after admission, and this examination should be repeated annually. The first examination at least, should include a roentgen examination of the chest

VI CURRICULUM

1 *Length of Course*—The minimum length of the course should be twenty-five calendar months (100 weeks) of full time training. The course should include not less than sixteen months (sixty-four weeks) of theoretical and technical work and not less than nine months (thirty-six weeks) hospital practice-training under competent supervision, all as set forth in detail in succeeding sections

2 *Distribution of Time*—The two years devoted to theoretical training should include not less than sixty semester hours, of which not less than thirty semester hours should consist of systematic instruction and not less than twenty-five hours of laboratory procedures. In special cases a variation of 10 per cent is permissible

3 The hours devoted to theoretical training should be still further subdivided as follows

	Semester Hours
(a) Biologic Sciences include	
Anatomy	15
Physiology	
Neurology	
Kinesiology	
Psychology	
Psychiatry	
(b) Social Sciences	4
(c) Theory of Occupational Therapy	4
(d) Clinical Subjects include	
Orthopedics	4
Tuberculosis	
Cardiac Diseases	
Blindness and Deafness	
Contagious Diseases (including Bacteriology if this subject is not given elsewhere)	
General Medical and Surgical Conditions	
(e) Electives	3
Total	30

4 Practical work in the various occupations should be allotted not less than twenty-five semester hours. The following subjects should be covered

Design	Leather
Textiles	Plastic Arts
Wood	Recreation
Metal	Miscellaneous

5 The curriculum outlined above should be in effect not later than Jan 1, 1939

ESSENTIALS FOR THE LISTING OF PHYSICIANS SPECIALIZING IN PATHOLOGY AND CLINICAL PATHOLOGY

Admission to the list is open to all physician-pathologists engaged in pathologic work in accordance with the "Essentials," whether connected with a hospital or not. The work of compiling a list of qualified pathologists according to these "Essentials" is done by the Council on Medical Education and Hospitals of the American Medical Association, 535 North Dearborn Street, Chicago

Definition—A physician holding himself out as a specialist in pathology may be defined as follows: One who is a graduate in medicine having had satisfactory training and experience in pathology, chemistry, bacteriology, or other allied subjects for at least three years subsequent to graduation who is in good standing and has been duly licensed to practice medicine.

Qualifications—(a) The pathologist shall be on a full or part time basis with a laboratory for the practical application of one or more of the fundamental sciences by the use of specialized apparatus, equipment and methods, for the purpose of ascertaining the presence, nature, source and progress of disease in the human body. He should devote the major part of his time to work in this field. (b) Pathology should be practiced on the same scientific and ethical basis, whether in the hospital or in a detached laboratory. The work represents the practice of medicine as in other specialties. The pathologist may make diagnoses only when he is a licensed graduate of medicine, has had satisfactory training and experience in pathology for at least three years subsequent to graduation from a medical college, is reasonably familiar with the manifestations of disease and is competent to make reliable reports.

(c) *Assistants*—The pathologist may have a corps of qualified assistants and technicians, responsible to him, and for whom he is responsible to carry out promptly, intelligently and accurately the several kinds of service the laboratory offers. All their reports, not only of tissues but also of all bacteriologic, hematologic, biochemical, serologic and pathologic data, should be made to the pathologist.

Scope—Pathologic service may consist of

- (a) Hematologic—Blood counts, blood groupings and coagulation tests and tests for blood parasites in general
- (b) Biochemical—Qualitative and quantitative analyses of urine, blood, gastric contents, body fluids, feces, intestinal contents and cerebrospinal fluids; renal and hepatic function tests and basal metabolism
- (c) Bacteriologic—Bacteriologic diagnoses, preparation of vaccines and blood and body fluid cultures
- (d) Serologic—Serologic diagnoses, agglutination, complement fixation or precipitin and lysis tests
- (e) Pathologic—Preparation of paraffin, celloidin or frozen sections, microscopic and gross pathologic specimens and necropsies
- (f) Parasitologic—Protozoal and zoological diagnoses
- (g) Metabolic—Disorders of metabolism
- (h) Cardiologic—Disorders of the heart

It is of course not required that the candidate shall be prepared to render all the services mentioned, since the work must necessarily be diversified in larger laboratories and in smaller laboratories it is not always practical to have equipment and setups that would be used only occasionally. Since many pathologists limit their work to one branch of the specialty, referring certain items far more efficiently is to be expected.

Reports—Reports should be made solely to the physician in charge of the patient and should be signed by the pathologist. All blanks and reports should have the name of the director printed on them and, if of a diagnostic or prognostic character, the name of the staff physician also.

Records—Full records of all examinations made by the pathologist, suitably indexed and filed, are essential. Every specimen analyzed in the laboratory should be given a serial number, which should follow that specimen in the records and reports. When the laboratory report concerns a hospital patient, an exact transcript of the laboratory record should be appended to the hospital case record. Each specimen submitted to the laboratory should be accompanied by pertinent clinical data.

Advertising matter should be directed only to physicians either through bulletins or through recognized technical journals and never to the nonprofessional public, as, for example, by announcements in popular journals and periodicals, circulars, pamphlets, telephone lists or other means.

DESCRIPTION OF MEDICAL COLLEGES

ALABAMA

University

UNIVERSITY OF ALABAMA SCHOOL OF MEDICINE.—Organized in 1859 at Mobile as the Medical College of Alabama. Classes graduated in 1861 and subsequent years excepting 1862 to 1868 inclusive. Reorganized in 1897 as the medical department of the University of Alabama. Present title assumed in 1907 when all property was transferred to the University of Alabama. In 1920 clinical teaching was suspended and the medical school was removed to the university campus near Tuscaloosa. Coeducational since 1920. Minimum entrance requirements are ninety semester hours of collegiate work. The course of study covers two years of thirty six weeks each. The faculty includes 13 professors and 10 instructors assistants etc a total of 23. The tuition fees are \$271 each year. Total registration for 1934-1935 was 130. The next session begins Sept 12 1935 and ends May 26 1936. The Dean is Stuart Graves M.D.

ARKANSAS

Little Rock

UNIVERSITY OF ARKANSAS SCHOOL OF MEDICINE 300 West Markham Street.—Organized in 1879 as the Medical Department of Arkansas Industrial University. Present title in 1899. In 1911 the College of Physicians and Surgeons united with it and it became an integral part of the University of Arkansas. The first class was graduated in 1880. Clinical teaching was suspended in 1918 but resumed in 1923. Coeducational since organization. The faculty consists of 34 professors and 65 lecturers and assistants total 99. The curriculum covers four years of nine months each. Entrance requirements are two years of collegiate work. The B.S. degree in medicine is conferred at the end of the second year. The fees for the four years for residents of Arkansas are \$200 nonresidents are charged \$150 additional each year. The total registration for 1934-1935 was 230 graduates 42. The next session begins Oct. 2 1935 and ends June 8 1936. The Dean is Frank Vinsonhaler M.D.

CALIFORNIA

Berkeley-San Francisco

UNIVERSITY OF CALIFORNIA MEDICAL SCHOOL University Campus Berkeley Medical Center San Francisco.—Organized in 1862 as the Toland Medical College. The first class graduated in 1864. In 1872 it became the Medical Department of the University of California. In 1909 by legislative enactment the College of Medicine of the University of Southern California at Los Angeles, became a clinical department but was changed to a graduate school in 1914. In 1915 the Hahnemann Medical College of the Pacific was merged and elective chairs in homeopathic materia medica and therapeutics were provided. Coeducational since organization. Three years of collegiate work is required for admission. The work of the first year is given at Berkeley and that of the last three years at San Francisco. The faculty is composed of 138 professors and 243 associates and assistants a total of 381. The course covers four years of eight months each and an additional fifth year consisting of an internship in a hospital or of special work in a department of the medical school. Fees for the four years respectively for residents of California are \$277 \$240 \$235 and \$235 nonresidents are charged \$300 additional each year. Total registration for 1934-1935 was 239 graduates 51. The next session begins Aug 26 1935 and ends May 22 1936. The Dean is Langley Porter M.D. San Francisco.

Loma Linda-Los Angeles

COLLEGE OF MEDICAL EVANGELISTS.—Organized in 1909. The first class graduated in 1914. The laboratory departments are at Loma Linda, the clinical departments at Los Angeles. Coeducational since organization. The faculty is composed of 59 professors and 237 associates assistants and instructors a total of 296. The course covers a period of five years including one year of internship. During the first and second years the students are in school twelve months each year. This is accomplished by means of the cooperative plan the student spending alternate months in an approved hospital in practical lines of medical training. Sixty four semester hours of collegiate work are required for admission. The total fees for the four years respectively are \$385 \$375 \$480 and \$440. The total registration for 1934-1935 was 404 graduates 83. The next session begins July 2 1935 and ends June 21 1936. The Dean of the Los Angeles Division is E. H. Risley M.D. and the Dean of the Loma Linda Division is W. E. Macpherson M.D.

Los Angeles

UNIVERSITY OF SOUTHERN CALIFORNIA SCHOOL OF MEDICINE, 3551 University Avenue.—Organized in 1885 as the University of Southern California College of Medicine. First class graduated in 1888. In 1908 it became the Medical Department of the University of California in Los Angeles. In 1909 the College of Physicians and Surgeons established in 1904 became the Medical Department of the University of Southern California. Its activities were suspended in 1920 reorganized in May 1928 under present title. The faculty consists of 132 professors and 126 instructors assistants and others a total of 258. An internship is required for graduation. Three years of collegiate work is required for admission. Coeducational since organization. Annual fees amount to \$450. The total registration for 1934-1935 was 176 graduates 35. The next session begins Sept 23 1935 and ends June 6 1936. The Dean is Paul S. McKibben Ph.D.

San Francisco

STANFORD UNIVERSITY SCHOOL OF MEDICINE 2398 Sacramento Street San Francisco.—Organized in 1908 when by agreement the interests of Cooper Medical College were taken over. The first class graduated in 1913. Coeducational since organization. The faculty consists of 109 professors and 156 lecturers assistants and others a total of 265. Three years of collegiate work is required for admission. The course covers four years of eight and one-half months each plus a fifth year of intern work. The fees for the four years, respectively are \$470 \$446 \$364 and \$364. The total registration for 1934-1935 was 220 graduates 47. The next session begins Sept 24 1935 and ends June 10 1936. The Dean is Loren Roscoe Chandler M.D.

COLORADO

Denver

UNIVERSITY OF COLORADO SCHOOL OF MEDICINE 4200 East Ninth Avenue.—Organized in 1883. Classes were graduated in 1885 and in all subsequent years except 1898 and 1899. Denver and Gross College of Medicine was merged Jan 1 1911. Coeducational since organization. The faculty is composed of 57 professors and 130 lecturers instructors and assistants a total of 187. The course covers four years of nine months each. The entrance requirements are three years of collegiate work. The fees for residents of Colorado for each of the four years are respectively, \$211 \$231 \$181 and \$191. Nonresidents are charged \$132 additional each year. The total registration for 1934-1935 was 205 graduates, 47. The next session begins Sept 30, 1935 and ends June 15 1936. The Dean is Maurice H. Rees M.D.

CONNECTICUT

New Haven

YALE UNIVERSITY SCHOOL OF MEDICINE 333 Cedar Street.—Chartered in 1810 as the Medical Institution of Yale College. Organized in 1812 instruction began in 1813 first class graduated in 1814. A new charter in 1879 changed the name to the Medical Department of Yale College. In 1884, the Connecticut Medical Society surrendered such authority as had been granted by the first charter. In 1887 Yale College became Yale University. Coeducational since 1916. The faculty consists of 127 professors and 180 lecturers and assistants a total of 307. The requirements for admission are three years of collegiate work. The course covers four years of nine months each. The fees for the four years respectively are \$500 \$500 \$500 and \$520. The total registration for 1934-1935 was 207 graduates 47. The next session begins Sept. 23 1935 and ends June 10 1936. The Dean is Stanhope Bayne-Jones, M.D.

DISTRICT OF COLUMBIA

Washington

GEORGETOWN UNIVERSITY SCHOOL OF MEDICINE 3900 Reservoir Road N.W.—Organized 1851. First class graduated in 1852. The faculty is composed of 55 professors 36 associate professors 3 assistant professors and 139 instructors total 233. Three years of collegiate work is required for entrance. The course of study covers four terms of eight and one-half months each. The present fees for each of the four sessions respectively are \$465 \$460 \$410 and \$450. The total registration for 1934-1935 was 493 graduates 113. The next session begins Sept 23 1935 and ends June 8 1936. The Dean is David V. McCauley S.J. Ph.D.

GEORGE WASHINGTON UNIVERSITY SCHOOL OF MEDICINE 1335 H Street N.W.—Organized in 1825 as the Medical Department of Columbian College. Also authorized to use the name National Medical College. Classes were graduated in 1826 and in all subsequent years except 1834 to 1838 and 1861 to 1863 inclusive. The original title was changed to Medical Department of Columbian University in 1873. In 1903 it absorbed the National University Medical Department. In 1904 by an act of Congress the title of George Washington University was granted to the institution. Coeducational since 1884. The faculty is composed of 54 professors and 110 instructors demonstrators and assistants a total of 164. Two years of collegiate work is required for admission. The course covers four years of thirty two weeks each. The fees for the four years respectively are \$500 each year. The total registration for 1934-1935 was 284 graduates 71. The next session begins Sept 25 1935 and ends June 6 1936. The Dean is Earl B. McKinley M.D.

HOWARD UNIVERSITY COLLEGE OF MEDICINE Fifth and W Streets N.W.—Chartered in 1867. Organized in 1869. The first class graduated in 1871. Coeducational since organization. Negro students compose a majority of those in attendance. The faculty comprises 30 professors and 79 lecturers and assistants 109 in all. The admission requirements are at least two years of collegiate work. The course covers four years of thirty three weeks each. The fees for each of the four sessions, respectively are \$269 \$269 \$269 and \$276. Registration for 1934-1935 was 171 graduates 55. The next session begins Sept 24 1935 and ends June 5 1936. The Dean is Numa P. G. Adams M.D.

GEORGIA

Atlanta

EMORY UNIVERSITY SCHOOL OF MEDICINE, 50 Armstrong Street and Druid Hills.—Organized in 1854 as the Atlanta School of Medicine. Classes graduated 1855 to 1861 when it suspended. Reorganized in 1865. A class graduated in 1865 and each subsequent year except 1874.

In 1898 it merged with the Southern Medical College (organized in 1878), taking the name of Atlanta College of Physicians and Surgeons. In 1913 it merged with the Atlanta School of Medicine (organized in 1905) reassuming the name of Atlanta Medical College. Became the Medical Department of Emory University in 1915 assumed present title in 1917. Two years of collegiate work is required for admission. The faculty consists of 19 professors and 168 associates and assistants, a total of 187. The course of study is four years of thirty-two weeks each. The fees for each of the four years are \$300. Total registration for 1934-1935 was 222 graduates 54. The next session begins Sept 30 1935 and ends June 8 1936. The Dean is Russell H. Oppenheimer M.D.

Augusta

UNIVERSITY OF GEORGIA SCHOOL OF MEDICINE, University Place.—Organized in 1828 as the Medical Academy of Georgia the name being changed to the Medical College of Georgia in 1829. Since 1873 it has been known as the Medical Department of the University of Georgia the name being changed July 1 1933 to University of Georgia School of Medicine. Property transferred to university in 1911. Classes were graduated in 1833 and all subsequent years except 1862 and 1863. Coeducational since 1920. The faculty includes 47 professors and 32 assistants 79 in all. Two years of collegiate work is required for admission. The course is four years of thirty-four weeks each. The fees for each of the four years are \$185 for residents of Georgia and \$365 each year for nonresidents. The total registration for 1934-1935 was 144 graduates 34. The next session begins Sept 23 1935, and ends June 8 1936. The Dean is G. Lombard Kelly M.D.

ILLINOIS

Chicago

LOYOLA UNIVERSITY SCHOOL OF MEDICINE 706 South Lincoln Street.—Incorporated in 1915 as the Bennett Medical College and operated as an organic part of Loyola University by virtue of an agreement entered into with the trustees of Bennett Medical College. Present title assumed in 1917. The Chicago College of Medicine and Surgery was purchased in 1917. The first class graduated in 1916. Coeducational. Two years of collegiate work is required for admission. The course of study is five years including an internship. The B.S. degree in medicine is conferred at the end of the third year. The faculty is composed of 55 professors and 238 assistants, lecturers, instructors and others a total of 293. The fees for each year are \$371 \$407 \$336 and \$298 respectively. The total enrollment for 1934-1935 was 487 graduates 96. The next session begins Sept 25 1935 and ends June 13 1936. The Dean is Louis D. Moorhead M.D.

NORTHWESTERN UNIVERSITY MEDICAL SCHOOL, 303 East Chicago Avenue.—Organized in 1859 as the Medical Department of Lind University. First class graduated in 1860. In 1864 it became independent as the Chicago Medical College. It united with Northwestern University in 1869 but retained the name of Chicago Medical College until 1891, when the present title was taken. Became an integral part of Northwestern University in 1905. Coeducational since 1926. The faculty comprises 116 professors 288 associates and instructors, a total of 404. The requirement for admission is three years of collegiate work. The B.S. degree in medicine is conferred at the end of the third year. The course covers four years of eight and one-half months each and a fifth year spent in an approved hospital as an intern or in other practical work. The total fees are \$361 each year. The total registration for 1934-1935 was 557 graduates 146. The next session begins Oct 1 1935, and ends June 13 1936. The Dean is Irving S. Cutter, M.D.

UNIVERSITY OF CHICAGO RUSH MEDICAL COLLEGE 1758 West Harrison Street.—Chartered in 1837 held first class in 1843. First class graduated in 1844. In 1887 the college became the medical department of Lake Forest University retaining however its self-government. This relation was dissolved in April 1898 and in the same month affiliation with the University of Chicago was established. Coeducational since 1898. Since that time the work of the first two years has been given on the University Quadrangles. In May 1924 by a new contract the University of Chicago took over the work of Rush Medical College as a department of the university. Thereafter only clinical work has been offered by Rush Medical College. Since 1914 the course has included a fifth year consisting of a hospital internship or of a fellowship in one of the departments. Three years of collegiate work is required for admission. The year is divided into four quarters of twelve weeks each the completion of the work of three of these quarters gives credit for a college year. The faculty is composed of 136 professors 147 associates instructors and others a total of 283. The fee for the third year is \$391 and for the fourth \$411. Total registration for 1934-1935 was 312 graduates 152. The next session begins Sept 30 1935 and ends June 16 1936. The school is in session all year except the month of September. The Dean is Ernest E. Irons M.D.

UNIVERSITY OF CHICAGO THE SCHOOL OF MEDICINE OF THE DIVISION OF THE BIOLOGICAL SCIENCES Fifty Eighth Street and Ellis Avenue.—Organized in 1924. The work of the first two years of the medical course has been given on the Quadrangles since 1899 in cooperation with Rush Medical College and that of the third and fourth clinical years was added in 1924 with the organization of this medical school and the construction on the Quadrangles of the university hospitals and clinics. Coeducational. A fifth year spent in successful internship in an approved hospital or in advanced work in some branch of medical science, is required for the degree of M.D. The faculty is composed of 98 professors 132 associates instructors and others a total of 230. The requirements for admission are three years of collegiate work. The B.S. degree in medicine is conferred at the end of the second year. The year is divided into four quarters of twelve weeks each the completion of the work of three of these quarters gives credit for a college year. Students are admitted at the beginning of the autumn quarter. The tuition fees for each of the

four years are \$375. Total registration for 1934-1935 was 339 graduates 34. The next session begins Oct 2 1935 and ends June 17, 1936. The Dean of Medical Students is B. C. H. Harvey M.D.

UNIVERSITY OF ILLINOIS COLLEGE OF MEDICINE, 1853 West Polk Street.—Organized in 1882 as the College of Physicians and Surgeons. The first class graduated in 1883. It became the Medical Department of the University of Illinois by affiliation in 1897. Relationship with the university was canceled in June 1912 and was restored in March 1913, when the present title was assumed. Coeducational since 1898. Two years of collegiate work is required for admission. The curriculum covers four years of thirty-two weeks each and a year of internship in an approved hospital. The B.S. degree in medicine is conferred at the end of the second year. The faculty is composed of 119 of professorial rank and 267 associates instructors and assistants a total of 386. The tuition is \$200 a year for students who are residents of Illinois \$300 a year for nonresident students. The total registration for 1934-1935 was 614 graduates 145. The next session begins Sept 30, 1935 and ends June 5, 1936. The Dean is David John Davis M.D.

INDIANA

Bloomington-Indianapolis

INDIANA UNIVERSITY SCHOOL OF MEDICINE.—Organized in 1903 but did not give all the work of the first two years of the medical course until 1905. In 1907 by union with the State College of Physicians and Surgeons, the complete course in medicine was offered. In 1908 the Indiana Medical College which was formed in 1905 by the merger of the Medical College of Indiana (organized in 1878) the Central College of Physicians and Surgeons (organized in 1879) and the Fort Wayne College of Medicine (organized in 1879) merged into it. The first class was graduated in 1908. Coeducational since organization. The faculty consists of 270 professors, lecturers associates and assistants. Two years of collegiate work is required for admission. The B.S. degree in medicine is conferred. The work of the first year is given at Bloomington and the work of the next three years at Indianapolis. The regular fee for the medical course for all four years is \$205 a year for residents of Indiana and \$410 for nonresidents. The total registration for 1934-1935 was 448 graduates 93. The next session begins Sept 17, 1935 and ends June 15 1936. The Dean at Bloomington is Burton D. Myers, M.D. and the Dean at Indianapolis is Willis Dew Gatch M.D.

IOWA

Iowa City

STATE UNIVERSITY OF IOWA COLLEGE OF MEDICINE, University Camps.—Organized in 1869. First session began in 1870. First class graduated in 1871. Absorbed Drake University College of Medicine in 1913. Coeducational since 1870. The faculty is made up of 46 professors 63 lecturers demonstrators and assistants a total of 109. Two years of collegiate work is required for admission. The B.S. degree in medicine is conferred. The course of study covers four years of thirty-four weeks each. The tuition fee is \$192 each year for residents of Iowa and \$456 for nonresidents. Total registration for 1934-1935 was 354 graduates 62. The next session begins Sept 23 1935 and ends June 1, 1936. The Dean is Ewen Murchison MacEwen M.D.

KANSAS

Lawrence-Kansas City

UNIVERSITY OF KANSAS SCHOOL OF MEDICINE.—Organized in 1880. It offered only the first two years of the medical course until 1905, when it merged with the Kansas City (Mo.) Medical College, founded in 1869, the College of Physicians and Surgeons, founded in 1894 and the Medico-Chirurgical College founded in 1897. Absorbed Kansas Medical College in 1913. First class graduated in 1906. The choical courses are given at Kansas City. Coeducational since 1880. The faculty includes 56 professors and 134 instructors assistants and others a total of 190. The requirement for admission is two years of collegiate work. The B.S. degree in medicine is conferred at the end of the second year. The course covers four years of nine months each. The total fees for residents of the state for each of the four years are respectively \$126 \$113 \$117 and \$120. For nonresidents the fees are \$196 \$192 \$205 and \$207. The total registration for 1934-1935 was 287 graduates 67. The next session begins Sept 19 1935 and ends June 8 1936. The Dean is H. R. Wahl M.D. Kansas City.

KENTUCKY

Louisville

UNIVERSITY OF LOUISVILLE SCHOOL OF MEDICINE, First and Chestnut Streets.—Organized in 1837 as Louisville Medical Institute. The first class graduated in 1838 and a class graduated each subsequent year except 1863. In 1846 the name was changed to University of Louisville Medical Department. In 1907 it absorbed the Kentucky University Medical Department in 1908 the Louisville Medical College, the Hospital College of Medicine and the Kentucky School of Medicine. In 1922 it changed its name to the University of Louisville School of Medicine. Coeducational since organization. Two years of collegiate work is required for admission. The faculty numbers 69 professors and 85 assistants instructors and others, a total of 154. Course covers four years of thirty-two weeks each exclusive of vacations and examinations. Fees for four years are, respectively \$389 \$389 \$394 and \$404. Total registration for 1934-1935 was 340 graduates 79. The next session begins Sept 19, 1935 and ends June 6 1936. The Dean is John Walker Moore, M.D.

LOUISIANA

New Orleans

LOUISIANA STATE UNIVERSITY MEDICAL CENTER 1532 Tulane Avenue.—Organized January 1931 Coeducational First session October, 1931 with students of first and third years Faculty comprises 30 professors and 125 assistant professors instructors and assistants a total of 155 Course covers four years of no less than 32 weeks each and one year of general rotation or laboratory internship in approved hospital A minimum of three years collegiate work is required for admission Total fees \$92 each year for residents of Louisiana additional tuition of \$300 each year for nonresidents Total registration for 1934-1935 was 301 graduates 19 The next session begins Sept 16 1935, and ends June 1 1936 The Dean is Arthur Vidrine MD

TULANE UNIVERSITY OF LOUISIANA SCHOOL OF MEDICINE 1430 Tulane Avenue.—Organized in 1834 as the Medical College of Louisiana Classes were graduated in 1835 and in all subsequent years except 1863 1865 inclusive It was transferred to the Medical Department of the University of Louisiana in 1847 and became the Medical Department of the Tulane University of Louisiana in 1884 Present title in 1913 Coeducational since 1915 The faculty comprises 30 professors and 135 associate and assistant professors instructors and assistants a total of 165 The course covers four years of thirty-two weeks each A minimum of two years of collegiate work is required for admission Total fees for each of the four years respectively are \$350 \$340 \$325 and \$355 The total registration for 1934-1935 was 471 graduates 125 The next session begins Sept 27 1935 and ends June 10 1936 The Dean is Charles Cassidy Bass MD

MARYLAND

Baltimore

JOHNS HOPKINS UNIVERSITY SCHOOL OF MEDICINE Washington and Monument Streets.—Organized in 1867 Offered preliminary course only until 1893 The first class graduated in 1897 Coeducational since organization The faculty consists of 73 professors and 307 instructors assistants and others a total of 380 The requirement for admission is a collegiate degree The course extends over four years of eight and one-half months each The total fees for each year are respectively \$621 \$620 \$620 and \$620 Total registration for 1934-1935 was 276 graduates 69 The next session begins Oct 1 1935 and ends June 9 1936 The Dean is Alan M Chesney MD

UNIVERSITY OF MARYLAND SCHOOL OF MEDICINE AND COLLEGE OF PHYSICIANS AND SURGEONS Lombard and Greene Streets.—Organized in 1807 as the College of Medicine of Maryland The first class graduated in 1810 In 1812 it became the University of Maryland School of Medicine Baltimore Medical College was merged into it in 1913 In 1915 the College of Physicians and Surgeons of Baltimore was merged and the present name assumed Coeducational since 1918 The faculty consists of 96 professors and 158 instructors and assistants a total of 254 Two years of collegiate work is required for admission The course covers four years of eight months each The fees for the four years respectively are \$410 \$400 \$400 and \$415 for residents of the state for nonresidents the fees are \$175 additional each year Total registration for 1934-1935 was 437 graduates 105 The next session begins Sept 24 1935 and ends June 6 1936 The Dean is J M H Rowland MD

MASSACHUSETTS

Boston

BOSTON UNIVERSITY SCHOOL OF MEDICINE 80 East Concord Street.—Organized in 1873 as a homeopathic institution In 1874 the New England Female Medical College founded in 1848 was merged into it The first class was graduated in 1874 Became nonsectarian in 1918 Coeducational since organization Three years of collegiate work is required for admission The faculty includes 20 professors 152 associates and others a total of 172 The course covers four years Total fees for each of the four years respectively are \$426 \$421 \$421 and \$435 Total registration for 1934-1935 was 253 graduates 55 The next session begins Sept 26 1935 and ends June 15 1936 The Dean is Alexander S Begg MD

HARVARD UNIVERSITY MEDICAL SCHOOL, 25 Shattuck Street.—Organized in 1782 The first class graduated in 1788 It has a faculty of 146 professors and 347 other instructors and assistants a total of 493 Two years of collegiate work is required for admission The total fee for each of the four years is \$400 plus \$5 the first year for matriculation The total registration for 1934-1935 was 523 graduates 137 The next session begins Sept 23 1935 and ends June 18 1936 The Dean is Charles Sidney Burwell MD

TUFTS COLLEGE MEDICAL SCHOOL, 416 Huntington Avenue.—Organized in 1893 as the Medical Department of Tufts College The first class graduated in 1894 Coeducational since 1894 It has a faculty of 75 professors and 256 assistants lecturers and others a total of 331 A bachelor's degree is required for admission The course covers four years of eight months each The total fees for each of the four years are \$412 \$407 \$407 and \$417 Total registration for 1934-1935 was 484 graduates 119 The next session begins Sept 25 1935 and ends June 15 1936 The Dean is A Warren Stearns MD

MICHIGAN

Ann Arbor

UNIVERSITY OF MICHIGAN MEDICAL SCHOOL.—Organized in 1850 as the University of Michigan Department of Medicine and Surgery The first class graduated in 1851 Present title assumed in 1915 Coeducational since 1870 It has a faculty of 26 professors 13 associate

professors 28 assistant professors 152 assistants instructors and lecturers a total of 219 The entrance requirements are ninety semester hours The curriculum covers four years of nine months each. HOSPITALS APPROVED FOR INTERNSHIPS IN THE DOMINION OF CANADA

For the benefit of graduates of approved medical colleges who desire an internship in Canada the Council on Medical Education and Hospitals of the American Medical Association has declared that hospitals which conform to the standards of the Department of Hospital Service of the Canadian Medical Association should be regarded as giving an internship equivalent in educational value to that offered by hospitals in the United States approved for intern training by the Council. It is understood however that this statement applies only to hospitals that are unqualifiedly approved under the Canadian plan and does not apply to that group referred to as Recommended.

The following list of hospitals revised to Jan 1 1935 has been furnished by the Department of Hospital Service

Name of Hospital	Location	Name of Hospital	Location	Name of Hospital	Location
Victoria General Hospital	Halifax, N S	Grace Hospital	Toronto Ont	Children's Hospital	Winnipeg Man
St John General Hospital	St John N B	Hospital for Sick Children	Toronto Ont	Winnipeg General Hospital	Winnipeg Man
Hospital du St Sacrement	Quebec Que	St Joseph's Hospital	Toronto Ont	St Boniface Hospital	St Boniface Man
Children's Memorial Hosp	Montreal Que	St Michael's Hospital	Toronto Ont	Regina General Hospital	Regina Sask
Hospital Notre Dame	Montreal Que	Toronto East General Hosp	Toronto Ont	Saskatoon City Hospital	Saskatoon Sask

NOTES

- 1 Women interns admitted
- 2 Women interns only
- (a) In lieu of maintenance
- (b) Bonus of \$110
- (c) Bonus of \$10 for satisfactory records
- (d) Salary established by government pay tables
- (e) \$25 per month for first 11 months \$28 the twelfth month
- (f) Bonus of \$25
- (g) Bonus of \$180
- (h) Bonus of \$100
- (i) Bonus of \$120
- (j) Bonus of \$20
- (k) \$25 per month second year
- (m) Bonus of \$50
- (n) Bonus of \$300
- (o) Bonus of \$150
- (p) \$20 per year less deductions
- (q) \$25 per month first year \$50 per month second year bonus of \$100
- (r) Bonus of \$50 on completion of 20 months service

- (s) \$15 per month for 6 months \$20 for 12 months bonus of \$100
- (t) Bonus of \$125
- (u) \$20 per month after completion of 12 months service
- (v) Bonus of \$200
- (w) Bonus of \$25
- (x) Bonus of \$200
- (y) Prefer aspirants going into foreign missions or boys born and raised in Hawaii
- (z) All internships reserved for the fifth year students of the College of Medicine University of the Philippines
- (1a) January, April May July August October and November
- (1b) January March July and November
- (1c) Quarterly
- (1d) April July and November
- (1e) Every two months
- (1f) January April and July
- (1g) January July and October
- (1h) January June July and September
- (1i) July August and September

- (1j) Surgery March July and November Medical January, April June and September
- (1k) January May and September
- (1l) January February June July and October
- (1m) June July and August
- (1n) Every six weeks
- (1o) July September and November
- (1p) January July and September
- (1q) July August, September and October
- (1r) March June September and December
- (1s) March July and November
- (1t) February July and November
- (1u) January June and September
- (1v) July August September November and December
- (1w) April June and August
- (1x) Appointments made by chief of office, The Panama Canal Washington D C Net salary \$70 per month

HOSPITALS APPROVED FOR RESIDENCIES IN SPECIALTIES

By the Council on Medical Education and Hospitals of the American Medical Association
Revised to Aug 31 1935

Note—The following hospitals are considered in position to furnish acceptable residencies in the several specialties designated for graduates who have already had a general internship or its equivalent in practice. A list of hospitals approved for internships will be found on pages 692-708. Statistical material is based on reports received for the calendar year 1934. Reported salaries should be verified through correspondence with individual hospitals.

The abbreviations under the column headed Control are as follows:

CyCo Corp
City and county Corporation unrestricted as to profit
Fed Frat Indiv
Federal Fraternal Individual

NPAssn Nonprofit association
Part Partnership
USPHS United States Public Health Service

1 Fellowships

2 Because of low death rate, autopsy figures not compiled

3 Includes urology

4 No salary first six months \$100 a month thereafter

5 Residences at Buffalo City Hospital are three year appointments

6 Including Internship Salary and bonus paid in lieu of maintenance

7 Usually twelve months but may be extended

8 Subject to reappointment

9 Salary established by government pay tables

10 Dental and medical degrees required

11 \$100 bonus

12 In lieu of maintenance

13 Includes obstetrics

14 One appointment is a fellowship

15 Includes pediatrics

16 University of Oregon Medical School Hospitals include Multnomah

17 County Hospital and Doernbecher Memorial Hospital for Children

18 (state control)

19 Two appointments are fellowships length of service indefinite

20 Includes medicine obstetrics and pediatrics

21 Includes psychiatry

22 Includes neurology

23 Not a hospital, outpatients only

24 Two years at Herman Kiefer Hospital Detroit in obstetrics

25 Two years at City of Detroit Receiving Hospital in gynecology

26 Affiliated with Barnes Hospital St. Louis gynecology

27 No salary first eight months \$25 a month last four months

28 Affiliated with Crippled Children's Hospital School and Hospital for

29 Crippled Adults, Memphis

30 Clinical material available through affiliation with Anthony N. Brady

31 Maternity Hospital Memorial Hospital St. Peter's Hospital and

32 St. Margaret's House and Hospital Albany and Hudson City

33 Hospital Hudson N. Y.

34 Affiliated with Infants Hospital and Boston Lying in Hospital

35 Boston

36 Includes neurosurgery

37 Two appointments are fellowships

38 Three months training in pediatric neurology at Emma Pendleton

39 Bradley Home East Providence

40 Three residents on roentgenology and three on radiation therapy

41 Training in radiation therapy only

42 Three appointments include four months on obstetrics

43 Two of the residents spend six months on surgery and six months

44 on urology

45 Includes six months on pathology

46 \$50 bonus

47 Three months on medical service at University Hospitals Minneapolis

48 First six months spent at New York Post Graduate Medical School

49 New York City

50 Includes dermatology syphilology

PROGRESS IN MEDICINE DURING THE
LAST TWENTY-FIVE YEARS

Three distinguished English physicians¹ have recently viewed in retrospect the major lines of advance in the fields of medicine, surgery, and obstetrics and gynecology, the occasion being the celebration of the jubilee of King George. There is in medicine, as in other lines of endeavor, a continuity of development that precludes the acceptance of any line of demarcation twenty-five years ago which is not based on previous accumulated experience.

In the recognition and practical applications of the deficiency diseases, including some of the anemias, a well-nigh new outlook has been reached. In the study of the hormones knowledge has progressed far, though, as Langdon-Brown points out, Starling's theory of chemical control of the body had been enunciated by 1905. The applications of chemistry and physics to medicine have also increased enormously during this time. The chemical analysis of the tissues, especially of the blood, has improved diagnosis, prognosis and treatment in manifold ways. The last twenty-five years has seen the dawn of a new era in psychotherapy, though internecine struggles and dictatorships have delayed its more general applications.

In surgery, as in medicine, much accomplishment can be visualized. Aside from technical improvements the physiologic relations of surgery have gained as compared with the anatomic. The application of such principles has been especially conspicuous in the fields of orthopedic, thoracic and plastic surgery. During this period roentgen therapy has developed remarkably as an aid to surgery, though its indications and limitations are not yet completely defined.

Fairbairn calls attention to the permeation of the fields of obstetrics and gynecology by the principles of constructive hygiene and preventive medicine. In the

knowledge and spread of the value of antepartum care, obstetrics has received one of its most useful adjuncts. Coincidentally there has been a trend toward conservatism in the management of the toxemias of pregnancy. The management of both normal and abnormal delivery itself has benefited much by improvement in bacteriologic and technical refinements. More precise knowledge of the relations between the hormones and the menstrual cycle has done much for gynecology. The application of the Aschheim-Zondek test in the diagnosis of early pregnancy is only one indication of the specific advantages that may be expected from further pursuit of these problems.

A constant dissatisfaction with knowledge may thus be tempered by the consideration of the progress that has actually occurred during the last twenty-five years. There is no ground for complacency, however, in the present state of our information, but it is pleasant to realize that, by comparison with the course of progress elsewhere, medicine has no cause to feel that it has stood still.

METHYLENE BLUE IN CYANIDE
POISONING

Agreement as to the mechanism of the action of methylene blue in cyanide poisoning has not yet been reached. Wendel¹ has studied this question by a series of carefully planned observations on dogs. He corroborated other observers in failing to note an accumulation of methemoglobin in the blood of dogs twenty minutes or more after intravenous injection of therapeutically employed quantities of methylene blue. In his opinion, however, this fact does not signify the nonformation of methemoglobin or its failure to play the essential part in the protective mechanism. In order to test this opinion, blood was withdrawn from normal dogs and defibrinated. The erythrocytes were separated from the serum by centrifugation, treated with physiologic solution of sodium chloride containing amyl nitrite to convert the hemoglobin to methemoglobin, freed from excess nitrite by repeated washing, and finally suspended in an equal volume of salt solution. This was reinjected intravenously into the animal from which it was taken either before or after injection of 1 minimum lethal dose of hydrocyanic acid (4 mg per kilogram subcutaneously). The two animals that received the cell suspension before the cyanide showed only mild and fleeting symptoms of poisoning, although less than three minutes was devoted to injection of the cyanide and the amount of cyanide injected was calculated to react with more than half of the methemoglobin in the circulation. A fraction of this quantity produces death in unprotected animals almost immediately. The two dogs that received cyanide before the cell suspension were quickly revived from advanced symptoms of poisoning. Recovery following injection

Ibid. p. 912. Fairbairn, J. S. Progress in Obstetrics and Gynecology During the Last Twenty Five Years. Ibid. p. 914.

¹ Wendel, W. B. Methylene Blue, Methemoglobin and Cyanide Poisoning. J. Pharmacol. & Exper. Therap. 54: 283 (July) 1935.

of methemoglobin-containing cells was much more rapid than that afforded by injection of either methylene blue or nitrite. It was thus demonstrated that cyanide reacts rapidly and firmly with intracorporeal methemoglobin *in vivo*.

The conflicting observations on methemoglobin accumulation following injection of methylene blue alone has led to confusion regarding the mechanism of its action in cyanide poisoning. In order to determine this action a dog was given 21 cc of a 1 per cent solution of methylene blue intravenously and shortly thereafter 1 minimum lethal dose of cyanide subcutaneously. The procedure was repeated about one hour and twenty minutes later with 14.5 cc of methylene blue and 1 minimum lethal dose of cyanide. Blood samples were collected before and after the injections. After centrifugation, the cells were washed twice with and suspended in sufficient Locke's solution to attain the original volume. The suspension of cells was then analyzed manometrically for oxygen capacity and spectrophotometrically for total pigment. The difference between these two values, the oxygen capacity being corrected for physically dissolved oxygen, is taken as a measure of preformed (in *vivo*) cyanmethemoglobin. About 70 per cent of administered cyanide was bound in the blood by methemoglobin. In another experiment a dog received subcutaneously in a single injection 2 minimum lethal doses of cyanide. This was followed by a slow continuous intravenous injection of 0.5 per cent methylene blue solution over a period of thirty minutes. In this instance 86 per cent of administered cyanide was bound in the circulating erythrocytes.

The apparently anomalous situation is explained by the known effects of cyanide on the reactions occurring within erythrocytes containing methylene blue. The principal action of methylene blue in counteracting the toxic effects of cyanide appears to depend, therefore, on methemoglobin formation. In the absence of experimental demonstrations that methylene blue can replace the cyanide-sensitive catalysts that are concerned with vital processes, the methemoglobin explanation appears to be all that is required.

CLINICAL ENDOCRINOLOGY

In February THE JOURNAL began publication of a series of articles on Glandular Physiology and Therapy, prepared under the auspices of the Council on Pharmacy and Chemistry. This series, which comprises thirty-two sections covering practically every known phase of endocrinology, is now completed and will soon be issued in book form. Preparation of the series was undertaken primarily to provide a convenient and authoritative source of information for physicians so that glandular therapy might be placed on a more rational plane. Investigators and teachers, however, will find it a valuable reference work. In addition, many of the reviews will be of assistance to the Council

on Pharmacy and Chemistry in evaluating the various endocrine preparations now so extravagantly extolled by pharmaceutical manufacturers. Almost without exception, the conclusions of the authorities in their respective fields have upheld the action of the Council in refusing to accept for New and Nonofficial Remedies, without more evidence, many of the widely used glandular products.

Commercial propaganda, together with an insufficient skepticism on the part of physicians, has led to widespread misapplication of present knowledge in endocrinology. Estrogenic and gonadotropic preparations are extensively employed in clinical syndromes in which they can hardly be expected to produce therapeutic benefit and in which they may even do harm. Commercial extracts of the adrenal cortex, recently shown to be practically devoid of the essential life-sustaining principle of the gland, are being used in the treatment not only of Addison's disease but even of such conditions as glaucoma. A variety of glandular products are administered by mouth, by which route many of them cannot be expected to prove effective even if they contain active material. Most of them do not! Pluriglandular products are widely employed with little rational basis and less therapeutic effect.

Misapprehensions in endocrinology are also extended to surgery and to radiology. The practice of partial adrenalectomy or adrenal denervation for the relief of hypertension, diabetes, hyperthyroidism, peptic ulcer and other conditions is by no means established as of value. Operation on this gland is an exceedingly hazardous procedure, and the mortality rates are most discouraging. The adrenal gland is essential to life, it lies in a nest of highly sensitive nerve structures. Even if therapeutic benefit might be expected to accrue from such surgical manipulations, the hazard to the life and health of the individual may prove greater than that of the disease it is proposed to alleviate. Furthermore, Addison's disease may be added to the original condition.

Radiologists have been irradiating the pituitary in the treatment of certain menstrual disorders, hypertension and other conditions, the adrenals have also been exposed to roentgen rays in the hope of lowering high blood pressure or decreasing the insulin requirement in diabetes. These procedures, too, may have effects more serious than the original disorder.

The cooperative efforts of the twenty-six authors who have prepared the series on Glandular Physiology and Therapy, in which all these questions are considered, should fill an important place in the armamentarium of both physician and investigator. Requests have been received from many foreign countries for the rights to translate this series of articles into other languages. It is hoped that American physicians will avail themselves of this book and use it as a guide to sound endocrine therapy.

Current Comment

HISTORY REPEATS IN AMERICAN MEDICAL EDUCATION

Thirty years ago there were in the United States 160 medical schools with an enrolment of 26,147. Ten years later, as a result of the investigations of the Council on Medical Education and of the publicity afforded by the Carnegie Foundation for the Advancement of Teaching, the number of schools had been reduced to ninety-six and the enrolment to 14,891. Shortly after 1918, when the war ended, there was manifested a tendency to increase, in 1925 the number of students was 18,200. During the academic year just closed it was 22,888. We have returned nearly to the place where we were when the Council was created. True, the number of schools has not increased with the growing enrolments of recent years. Our 23,000 medical students today are distributed among fewer and better medical schools than were the students of a generation ago. But the factors that caused such deplorable conditions then are evidently again at work. These factors are the almost complete dependence on the income from tuition fees for the maintenance of the school and consequent failure to limit admissions to carefully selected and well qualified students. Unless this tendency is overcome there must result, inevitably, a lowering of the standards of medical education and practice. The tendency has been receiving the attention of the Council. Educators, state boards of examination, physicians and public authorities may well also give it their consideration.

INCOMPLETE SCHOOLS

When the American Medical Association undertook, more than a quarter of a century ago, to appraise the medical schools of that day, some were located in small communities where, for obvious reasons, clinical material sufficient for teaching purposes was not available. Such schools, therefore, finding themselves quite unable to carry out the full four-year program of medical instruction, restricted their efforts to the first two years of the curriculum. At that time the first two years were wholly occupied with preclinical subjects, such as anatomy, physiology and chemistry. In recent years there has been, among those schools teaching the full course, a strong trend in the direction of bringing the clinical subjects into closer coordination with the preclinical. This means that physical and laboratory diagnosis are usually taught in the second year, that gross and microscopic anatomy are likewise a part of the second year curriculum, and that introductory clinical lectures are closely correlated with the so-called laboratory subjects. Those schools which, because of their limitations, offered only two years of medicine were unable to participate in this development because, located as they were, clinical facilities were nonexistent. It has become increasingly difficult for the students of such institutions to make the transfer that is necessary to enable them to complete their training. The present

status of these incomplete schools is therefore unsatisfactory. With the completion of the current survey of medical education it is hoped that a solution of this problem will be found.

NEW OBJECTIVES FOR THE BUREAU OF THE CENSUS

For about a third of a century the fundamental task of the Bureau of the Census in the field of vital statistics was to extend the registration areas for births and deaths. With the completion of both areas in 1933, when Texas was admitted, the primary responsibility of the bureau was ended. New tasks are now to be undertaken, and a reorganization of the division of vital statistics has been announced. The Bureau of the Census now looks forward to country-wide registration as a means of furnishing comprehensive data for the first time. More intensive efforts are foreseen in analyzing the data and presenting more refined results, thus giving a better statistical basis for public health work and for studies of changes in the structure of the population. It is still necessary, however, to work toward more accurate and complete recording of births and deaths. Physicians are vitally interested in the Bureau of the Census, since they initiate the reports on which figures compiled by the bureau must be based. The medical profession may well endorse the stated ambition of the director of the census "to build up the bureau to a point where it may, without challenge, be regarded as the best statistical organization in the world."¹

GRADUATE SCHOOLS OF MEDICINE

Growing demands for training in special fields of medicine have given greater significance to the available types of graduate instruction. To present, as clearly as possible, a picture of existing opportunities for advanced study, the Council on Medical Education and Hospitals has obtained reports from all universities having faculties of medicine and has presented the results in table 16 of its report in this issue (page 689). Two universities have separately organized graduate schools of medicine. Twenty-nine report that they offer systematic courses of instruction for physicians. An apprenticeship type of training through residencies or fellowships is available in fifty-three institutions. Extension teaching of a less formal sort is conducted by nineteen schools, and as many more do not engage in any form of postgraduate work. Graduate teaching is a heavy tax on the resources of an institution, and not many of our schools are equipped to engage extensively in this work. This is particularly true of the intensive courses demanded by physicians who have already engaged in practice. Generally speaking, they are able to pay in cash for what they want, but because of greater earning power and social responsibilities they cannot devote any unnecessary time to this phase of training. Younger men who have never practiced may be quite willing to pay for experience with time and services after the traditional manner of apprentices.

¹ Department of Commerce, Bureau of the Census. Communication "To Those Professionally Interested," under date of July 1, 1935.

Association News

RADIO BROADCASTS

The American Medical Association will broadcast over the Blue network of the National Broadcasting Company at 5 p. m. eastern standard time (4 o'clock central standard time, 3 o'clock mountain time) October 1 and each Tuesday thereafter, presenting a dramatized program with incidental music under the general theme of "Medical Emergencies and How They Are Met." The title of the program will be *Your Health*. The program will be recognizable by a musical salutation through which the voice of the announcer will offer a toast: "Ladies and Gentlemen, Your Health!" The theme of the program will be repeated each week in the opening announcement, which informs the listener that the same medical knowledge and the same doctors that are mobilized for the meeting of grave medical emergencies are available in every community, day and night, for the promotion of the health of the people. Each program will include a brief talk dealing with the central theme of the individual broadcast.

The October schedule is as follows:

October 1	Burns	Morris Fishbein M.D.
October 8	Hazards from Foreign Shores	W. W. Bauer M.D.
October 15	Unconsciousness	Morris Fishbein M.D.
October 22	Asphyxiation	W. W. Bauer M.D.
October 29	To be announced	

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

CONNECTICUT

One July Fourth Accident—One injury from a Fourth of July accident was reported in New Haven this year, as compared with a record of one death and 103 injuries in fireworks accidents in 1934. The reduction is credited to the city's new fireworks ordinance, which forbids the use and sale of fireworks and which was adopted by the board of aldermen following an educational campaign sponsored by the New Haven Department of Health. The educational campaign last year followed a meeting of representatives of civic organizations with the department of health, July 18, at which a resolution was adopted urging the passage of the ordinance. The one injury this year was that of a policeman, who was slightly injured when taking a blank cartridge pistol from a youth in the act of discharging it.

The Eleventh Clinical Congress—The Connecticut State Medical Society will hold its eleventh clinical congress in New Haven, September 17-19. A commercial exhibit will be shown in the new Tompkins East I of the New Haven Hospital, a new feature this year. Afternoon sessions each day will be devoted to demonstrations and round table discussions by Connecticut physicians on the subjects discussed at the morning sessions. Papers will be read by the following physicians:

William D. Stroud	Philadelphia	Factors That Lead to Vascular Degeneration
Herrman L. Blumgart	Boston	Value of Total Thyroidectomy in Treating Patients with Congestive Heart Failure and Angina Pectoris
Perrin H. Long	Baltimore	The Common Cold
Soma Weiss	Boston	Clinical Use of Sedatives with Particular Reference to the Barbituric Acid Derivatives
Donald Munro	Boston	Modern Treatment of Cranio-cerebral Injuries with Especial Reference to the Maximum Permissible Mortality Rate
Frank H. Lahey	Boston	Newer Conceptions of Anesthesia and Anesthetists
Dudley Merrill	Boston	Dangers Inherent in the Clinical Diagnosis of Cancer
Dana W. Atchley	New York	Occurrence and Treatment of Shock in Clinical Medicine
Edward A. Schuman	Philadelphia	Labor
Charles Hendee Smith	New York	Care of the Tuberculosis of Childhood in the Home
Francis W. O'Connor	New York	Common Parasitic Diseases in the New England States
John J. Moorhead	New York	Early Treatment of Fractures of Long Bones

At one evening session, Dr. Louis P. Hamburger, associate in medicine, Johns Hopkins University School of Medicine, Baltimore, will speak on "The Importance of a Discussion of Minor Ailments in the Medical Curriculum."

GEORGIA

Date of Annual Meeting Changed—To avoid conflict with the annual session of the American Medical Association, the eighty-seventh annual meeting of the Medical Association of Georgia will be held April 21-24, 1936, instead of May 11-15 as previously announced.

Campaign Against Diphtheria—The state department of health is conducting an immunization campaign against diphtheria, it is announced. In a statement urging parents to cooperate with the department, the director of public health, Dr. Thomas F. Abercrombie, Atlanta, points out that the death rate from diphtheria has increased from 4.6 per cent in 1930 to 6 per cent in 1934.

Society News—Dr. William W. Anderson, Atlanta, was elected president of the Georgia Pediatric Society at the recent annual meeting, and Dr. Roger W. Dickson, Atlanta, was named secretary. The next annual session will be held at Atlanta. At a meeting of the First District Medical Society in Savannah, July 17, speakers included Drs. Carl C. Aven, Atlanta, on "Prevention and Treatment of Lung Abscesses," and John D. Martin Jr. and Alfonso J. Mooney Jr., Atlanta, "Tannic Acid Treatment of Burns." The Spalding County Medical Society was addressed at Griffin, June 18, by Drs. Thomas P. Goodwyn and Henry Walker Jernigan, Atlanta, on "Fractures of the Ankle." Speakers before the Fourth District Medical Society at Warm Springs, August 7, included Drs. David Henry Poer, Atlanta, treatment of thyroid diseases and Charles E. Irwin, problems of poliomyelitis. Dr. Leonard R. Massengale read a paper on "Acute Glomerulonephritis" before the Randolph County Medical Society in Cuthbert, August 1. At a meeting of the Tenth District Medical Society in Elberton, August 14, speakers included Drs. Joseph E. Johnson Jr., Elberton, on chorea, and Henry W. Birdsong, Athens, agranulocytosis.

ILLINOIS

Public Health Survey—Illinois will receive \$425,000 from a federal appropriation of \$3,450,000 for a public health survey in representative urban and rural communities under the Works Progress Administration. A house to house canvass will be made to determine the prevalence of chronic diseases and illnesses of long standing in samples of the general population of various income levels. Physical examinations of a smaller sample of the surveyed persons will be made by physicians to supplement available hospital records to evaluate the accuracy of the canvass reports. A survey of medical facilities will also be made, with especial reference to chronic diseases.

Chicago

Personal—Dr. Hubbard Prather Saunders is the winner of the VanDerslice Cup of the Chicago Medical Society with a gross score of 80. Dr. Saunders and Dr. Frank S. Needham tied for first place with an 84 in the society's annual golf tournament at the Medinah Country Club, August 7, and the tie was played off, August 13.

IOWA

Society News—The Linn County Medical Society will be addressed, September 12, by Dr. John F. Erdmann, New York, on "Cholecystitis, Cholangitis, Choledochitis." Speakers before the Buchanan County Medical Society, July 18, were Drs. Joseph G. Mayo and Hugh Cabot, both of Rochester, Minn., on hyperinsulinism and tuberculosis of the genito-urinary tract, respectively. At a meeting of the Dallas Guthrie Counties Medical Society, July 30, Dr. John T. Strawn, Des Moines, discussed carcinoma of the stomach and Dr. Keith W. Diddy, Perry, differential diagnosis of acute conditions of the upper part of the abdomen. At a joint meeting of the Dickinson and Emmet county medical societies in Estherville, July 18, speakers were Drs. Oscar H. Miller, Estherville, on aplastic anemia, Elam E. Lashbrook, Estherville, purpura, and William E. Bullock, Lake Park, hemophilia. Dr. James B. Carey, Minneapolis, discussed the anemias before the Floyd County Medical Society at a meeting in Charles City, July 23.

KENTUCKY

Personal—Dr. Theodore W. Singer, Louisville, celebrated his one hundredth birthday July 25. Dr. Singer was born in Cleveland and studied medicine at Hudson Medical College, which became a part of the Western Reserve University School of Medicine. He has practiced in Cleveland, Milwaukee and Chicago and still has a limited practice, it is reported. He served in the Civil and Spanish-American wars. A group of physicians headed by Dr. Leon L. Solomon gave a small reception for Dr. Singer on his birthday.

Society News—A graduate course in pediatrics was presented before the Hopkins County Medical Society, Madisonville, June 19, by Drs Philip F Barbour and Harry S Andrews, Louisville. Dr Barbour discussed birth injuries, appendicitis in children and rheumatism. Dr Andrews anemias in children, communicable diseases and diarrhea.—Drs Wallace Frank and Charles D Enfield Louisville, as guest speakers discussed cancer before the Seventh District Medical Society in Somerset June 20.—At a meeting of the Muldraugh Hill Medical Society at Elizabethtown August 8, speakers were Drs Nelson D Widmer, Lebanon "Medical Treatment of Peptic Ulcer," Walter I Hume Louisville "Thyroid Problems," Virgil E Simpson, Louisville, "Preview of Economic Security in Kentucky" and William Hamilton Long, Louisville, "Status Lymphaticus"

MASSACHUSETTS

Relief Project for Physicians—The *New England Journal of Medicine* announces a plan whereby resident physicians of Boston who are in urgent need of financial relief will be given medical employment. The project will be maintained by the state emergency relief association and will be under the direction of Dr Charles F Wilensky of the Boston Health Department. Applicants must be legal practitioners of medicine residents of Boston, and in such financial need that they are eligible for aid from the emergency relief association. Applications should be made first to the secretary of the proper district medical society.

MICHIGAN

Grants to University—Fourteen thousand dollars has been appropriated by the Rockefeller Foundation to the University of Michigan for study of the application of spectroscopic methods to medical problems under the general direction of Dr Louis H Newburgh professor of clinical investigation in internal medicine, and Harrison M Randall, Ph.D., professor of physics University of Michigan Ann Arbor. Funds not to exceed \$5,000 annually have been provided for a five year period to end June 30 1940 for special research in the physiology of respiration under the direction of Dr Robert Gesell.

Uncommon Diseases Reported—Although in very small numbers the following variety of diseases have been reported to the Detroit Health Department since January 1: one case of leprosy, eleven cases of undulant fever, twenty-one cases of malaria and, since April 1 nine cases of typhoid. One paratyphoid fever carrier was reported and four carriers of typhoid. Thirteen cases of amebic dysentery have been recorded since January 1 four cases of trichinosis, three cases of tularemia, and one case of tetanus. The department points out that the last case of smallpox reported in Detroit was on Aug 3, 1931, and the last death from this disease occurred in 1925.

The Children's Institute—The work of caring for orphan children in Michigan will in the future be handled in Ann Arbor under the name of the Michigan Children's Institute, in accordance with recent legislation. These children have in the past been housed in an institution in Coldwater. Under the new plan, an attempt will be made to have them placed in private homes so that they may be brought up in a more normal condition than that provided in an institution. Ann Arbor was selected because the University Hospital can give the medical and psychologic examinations necessary for successful placement. It was reported that the state welfare commission had available \$202,840 for the project. A large residence with accommodations for about thirty children will be maintained in the city for temporary shelter.

MINNESOTA

Personal—Dr Charles R Drake has been elected president of the Minneapolis board of education.—Dr William W Will Bertha newly elected president of the Minnesota State Medical Association was recently guest of honor at a dinner given by the Todd County Medical Society.

Society News—Dr Eugene T Leddy Rochester, was elected president of the Minnesota Radiological Society at its annual meeting in Minneapolis June 24. Dr John Richards Aurelius St Paul vice president and Dr Leo G Rigler, Minneapolis secretary.—At a meeting of the Scott-Carver Counties Medical Society in Arlington July 9 Dr Harry G Irvine Minneapolis discussed therapy of dermatitis and Dr Earl A Loomis Minneapolis diseases of the eye, ear, nose and throat.—At the annual meeting of the Wabasha County Medical Society at Old Frontenac, July 11, speakers included Drs Rudolph C Radabaugh, Hastings. Fecal Impaction. Following Cholecystitis. Alfred E. Belitz, Pepin, Wis., Breech Presentation. George A. Earl, St. Paul, "Injection

Method versus Open Treatment of Hernia', Harold E. Hullsiek St Paul, "Diagnosis and Office Treatment of Diseases of the Rectum," and Edward H Rynearson, Rochester, "Summary of the Present Knowledge of the Hormones of the Anterior Lobe of the Pituitary Gland"

MISSISSIPPI

Society Makes Rules for Members Testifying in Malpractice Suits—The Central Medical Society recently adopted a resolution forbidding its members to give voluntary evidence in any malpractice action, unless the proposed testimony has been previously examined and approved by those designated by the society for the purpose. In an action of this sort, the president of the society will appoint an "investigator" to call on medical witnesses of the plaintiff to submit to him their proposed testimony in writing. The investigator after impartial consideration will submit the testimony and his opinion to three members who will be known as "consultants." If the results of the investigation and the opinion of the consultants support the testimony on the part of the plaintiff, the physician will be encouraged to testify, on the other hand should the report indicate that the proposed testimony will wrongfully disparage the defendant's reputation and will not serve justice, the plaintiff's physician will be notified that the testimony is not approved and that members of the society will so state in court. If, irrespective of this decision and advice the testimony deemed objectionable is given, the member giving it will be expelled from the society for unprofessional conduct.

MISSOURI

Joint Health Meeting—The Missouri Public Health Association and the Missouri Tuberculosis Association will hold a joint session at the Muehlebach Hotel Kansas City, September 5-7. The following persons will speak:

William De Kleene, M.D. medical adviser, American Red Cross Washington D C. The Medical and Health Aspect of Red Cross Disaster Work.
Paul A Witte, Ph.D. Chicago Relation of Mental to Physical Health.
Caroline Hedger, M.A. Chicago Health of the Adolescent.
Edwin Lee Miller, M.D. Kansas City The State and Public Health.
Reginald M Atwater, M.D. New York Team Work in Public Health.
Chester A Stewart, M.D. Minneapolis The Lymanhurst Interpretation of Tuberculosis.

NEW YORK

Personal—Dr Harold Jackson Davis, assistant director of local health administration of the state department of health Albany has been assigned as part-time consultant in medical care to the Works Progress Administration. Dr Davis will pass on the professional aspects of all projects of the administration submitted from upstate New York, which involve the employment of physicians, dentists, nurses and other health workers on a security wage. He will act also as liaison officer between the administration, the state and local departments of health and the state, and local medical and other professional societies. He will serve also as technical adviser to the state compensation officer in regard to the professional aspects of the medical care and treatment provided to workers of the Works Progress Administration who are disabled in line of duty.

New York City

Course in Psychoanalysis—The New York Psychoanalytic Institute announces an introductory course in 'Psychoanalysis in Medicine' for physicians, to begin October 3 and continue for twelve Thursdays except November 28. The lectures will be given by Drs Clarence P Oberndorf, A A Brill Sandor Lorand and Philip R. Lehman.

Changes at New York University—The following promotions were recently announced by New York University College of Medicine:

Dr James A Shannon to be assistant professor of physiology.
Dr Meyer J Kautsky assistant clinical professor of surgery.
Dr Edward M Livingston assistant clinical professor of surgery.

A plan for graduate study in radiology leading to the degree of doctor of medical science was approved at a recent meeting of the council and added to the list of similar courses already offered in other departments.

Opening for Bacteriologist—The Municipal Civil Service Commission announces an examination for the position of associate director of the bacteriologic laboratories in the health department. Applications will be received up to October 4, and the dates for the examination will be announced later. All qualified citizens of the United States are eligible for the examination, but the appointee must reside in New York after he has accepted the position. Applicants must be not more than 55 years of age and have not less than five years of satisfactory

experience in a bacteriologic laboratory of recognized standing. Applications should be sent to William H. Allen, secretary, Municipal Civil Service Commission, Room 1400, Municipal Building, Manhattan. An examination for the position of director of the division of psychiatry, department of hospitals, Bellevue Hospitals, was announced in *THE JOURNAL*, August 10, page 443.

PENNSYLVANIA

District Meetings—Dr. Nathan B. Van Etten, New York, Speaker of the House of Delegates of the American Medical Association, addressed the annual meeting of the Third Council District of the Medical Society of the State of Pennsylvania at Skytop Lodge in the Pocono Mountains, July 31, on medical economics. Officers of the state society also made addresses and the afternoon was spent at golf, tennis, cards, shooting, bathing, horseback riding and quarts. At a meeting of the Fourth Council District at Eagles Mere, July 11, speakers included Drs. Moses Behrend, Philadelphia, on "Open Operation for Fractures", Stuart W. Harrington, Rochester, Minn., "Clinical Diagnosis and Surgical Treatment of Tumors of the Breast," and Walter F. Donaldson, Pittsburgh, secretary of the Medical Society of the State of Pennsylvania, "County Medical Society Membership—A Privilege and a Social Obligation."—The Eighth and Ninth Council Districts of the Medical Society of the State of Pennsylvania held a combined meeting at the Pinecrest Country Club near Brookville, August 1. The following speakers were on the scientific program: Drs. Joseph A. Hepp, Pittsburgh, on "Differential Diagnosis of Leukorrhea", James Andrew Merle Russell, Erie, "Deafness", John W. Shirer, Pittsburgh, "Present Status of Endocrine Therapy," and Hubert C. King, Lakewood, Ohio, "Manifestations of Heart Failure in Middle Life." Officers of the state society discussed organization problems.

Philadelphia

Personal—Dr. Stanley P. Reimann, director of the Lankenau Hospital research laboratory, has gone to Germany to attend cancer conferences at the biologic laboratory at Oppau, near Heidelberg. He will also visit the Free Cancer Hospital in London.

Medical Seminars Deferred—The Philadelphia County Medical Society announces that the opening of its first medical seminar, on "Laboratory Methods and Clinical Application," has been postponed until November 29. This change has been made in view of the seminars on anesthesia that will be offered by the Philadelphia County Dental Society on six consecutive Fridays beginning October 18. The medical society will start its second seminar on Friday afternoon, January 3. Parasites will be the theme of this series. The duration of these seminars will be four Fridays.

UTAH

State Medical Meeting at Logan—The forty-first annual meeting of the Utah State Medical Association will be held in Logan, September 5-7, with headquarters at the Hotel Eccles and under the presidency of Dr. David C. Budge, Logan. The following guest speakers will present the program:

- George E. Brown, M.D., Rochester, Minn., General Survey of Diseases of the Blood Vessels; Disorders of the Sympathetic Nervous System; Recent Developments in Investigations of Essential Hypertension.
- Dean D. Lewis, M.D., Baltimore, Diseases of the Blood Vessels (Surgical); Differential Diagnosis of Bone Tumors; Differential Lesions of the Breast.
- Karl F. Meyer, Ph.D., San Francisco, Sepsis; Present Status of Undulant Fever.
- Claude F. Dixon, M.D., Rochester, Minn., Surgical Lesions of the Colon; Motion Picture Demonstration; Management of Acute Appendicitis; Prevention and Curative Measures Against Peritonitis.
- George H. Gardner, M.D., Chicago, Retrodisplacement of the Uterus, Its Significance, the Indications for Treatment and the Choice of Treatment; Uterine Fibroids; Leukorrhea; Differential Diagnosis and Treatment.
- William H. Holmes, M.D., Chicago, Common Neurologic Syndromes; Bright's Disease.
- John A. Wolfer, M.D., Chicago, Consideration of the Nutritional Status of the Surgical Patient; Pancreatic Juice as a Factor in the Etiology of Gallbladder Disease.
- William R. Cubbins, M.D., Chicago, Injured Cruciate Ligaments of the Knee Joint; Diagnosis and Methods of Repair; Fractures of the Humerus and Both Bones of the Arm; Fractures of the Acetabulum and Pelvis.

Dr. Meyer will address an evening public meeting at Logan Tabernacle, September 5, on "Plagues, Past and Present," illustrated by motion pictures. There will be a banquet Friday evening. The women's auxiliary to the society will hold its annual session Thursday and Friday.

WISCONSIN

Drive Against Diphtheria—The Milwaukee County Medical Society and the county health department conducted their annual campaign against diphtheria, July 15 to August 15. The city has had only fourteen cases thus far this year, it was said. Seventy-five clinics were to be held and it was hoped to immunize 7,500 children.

State Medical Meeting at Milwaukee—The ninety-fourth annual meeting of the State Medical Society of Wisconsin will be held in Milwaukee, September 17-20, at the Milwaukee Auditorium. The preliminary program announces the following guest speakers with their subjects:

- Dr. Fred L. Knowles, Fort Dodge, Iowa, Treatment of Fracture of the Neck of the Femur.
- Dr. Albert Graeme Mitchell, Cincinnati, Nonspecific Factors Affecting the Tuberculin Reaction.
- Dr. Arthur J. Patek, Jr., Boston, Present Day Concepts in the Treatment of Anemia.
- Dr. Aaron Arkin, Chicago, Tumors of the Lung and Their Differential Diagnosis.
- Dr. Uras V. Portmann, Cleveland, Factors that Influence the Curability of Cancer.
- Dr. Louis G. Herrmann, Cincinnati, Treatment of Peripheral Vascular Diseases.
- Dr. Ernest M. Hammes, St. Paul, Spinal Cord Injuries.
- Dr. Henry W. F. Woltman, Rochester, Minn., Some Neurologic Post-operative Complications.
- Dr. Frederick A. Collier, Ann Arbor, Mich., Water Balance of Sick Patients.
- Dr. Simon Levin, Houghton, Mich., Dangers and Their Prevention in Operative Treatment of Goiters.
- Dr. Charles M. McKenna, Chicago, Operative Technic for Cryptorchidism.
- Dr. Vernon C. David, Chicago, Surgical Aspects of Carcinoma of the Rectum and Sigmoid (part of a symposium).
- Dr. Fremont A. Chandler, Chicago, Aseptic Necrosis of the Head of the Femur.
- Dr. Percival Bailey, Chicago, Peculiarities of Intracranial Tumors in Childhood.
- Dr. Harold E. Robertson, Rochester, Minn., Value of Postmortem Examination to the Practice of Medicine.
- Dr. Waltham Walters, Rochester, Operative Procedures Indicated in the Treatment of Peptic Ulcers.

Other visiting speakers will be Drs. Hugh Cabot and Gershom J. Thompson, Rochester, Minn., on the scientific program, and Dr. Edward H. Carv, Dallas, Texas, who will speak at the annual banquet at the Hotel Schroeder, Thursday evening, September 19. Dry clinics will be held at the Milwaukee County Hospital and the Milwaukee Children's Hospital Wednesday morning. There will be a hobby exhibit arranged by the Medical Society of Milwaukee County.

PUERTO RICO

Personal—Dr. William Branch Porter, professor of medicine, Medical College of Virginia, Richmond, Va., has spent the past two months in San Juan, Puerto Rico, doing special investigative work on the blood flow in cases of anemia. Dr. Porter has carried on his experiments among patients hospitalized in the University Hospital of the School of Tropical Medicine, Mimiya Clinic and the Municipal Hospital.

Pan American Medical Congress—En route to New York City from its cruise to Rio de Janeiro, Brazil, the Sixth Floating Congress of the Pan American Medical Association stopped off at San Juan, Puerto Rico, July 29. The School of Tropical Medicine contributed as its share in the entertainment program for the Congress a series of exhibits of the various phases of tropical diseases, on which the faculty of the school has been working. All departments of the school were represented. After viewing the exhibits the visitors attended a symposium on tuberculosis, held under the auspices of the insular department of health.

Monthly Hospital Staff Conferences—The medical men on the staffs of the various hospitals of San Juan, have planned a series of conferences, one of which will take place every month. These conferences are to be limited to scientific problems of actual interest in the daily work of the physicians taking part. At the last conference, August 9, the following program was presented:

- Dr. Isaac F. Gonzalez Martinez, Ray, Studies of Ulcers of the Duodenum.
- Dr. Manuel Diaz Garcia, Surgical Aspects Presented in an Operation for Ulcers of the Duodenum.
- Dr. Antonio Martinez Alvarez, Histopathologic Study of the Autopsies of Three Cases of Intestinal Perforation.

Four New Hospitals for the Indigent—Governor Blanton Winship of Puerto Rico has approved a project of the house of representatives (P. de la C. 55) authorizing the construction of four district hospitals to care for the indigent sick of the island. The administration of these hospitals will be vested in a board of seven members appointed by the governor, two will be ex officio members from the insular legislature, one will be a lawyer, one an engineer, one a pharmacist.

and the other two doctors of more than three years' experience. The construction of these hospitals is to be financed by a half a million dollar loan, their maintenance afterward to be cared for by special appropriations made from the yearly insular budget

GENERAL

Committee to Study Sex Variants—Announcement is made of the establishment of a committee for the study of sex variants with Dr Eugen Kahn, Sterling professor of psychiatry and mental hygiene, Yale University School of Medicine, New Haven, as chairman. The committee will correlate the various scientific interests in this field, serve as a scientific sponsoring agency to further research on sexual variation, and appoint advisory subcommittees for projects sponsored or to be sponsored by the committee. A study of homosexuals of cultured background is already under way. The committee will be glad to consider any research projects that may be presented, which have a bearing on the physiologic, psychologic, psychiatric or sociological problems of sex variants, and to act in a sponsoring and advisory capacity should such projects be approved. All communications should be addressed to the secretary, Dr Robert W Laidlaw at 199 Fort Washington Avenue, New York City. Dr Laidlaw and Dr Kahn, together with the treasurer, Carney Landis, Ph D, Columbia University, Dr Robert L Dickinson of the National Committee on Maternal Health and Dr Josephine H Kenyon, New York University, constitute the executive committee.

Sight Conservation Activities—According to the annual report of the National Society for the Prevention of Blindness, for the first time, executives of practically all national safety, health and recreation agencies concerned with accidents from fireworks conferred on methods of procedure to eliminate such casualties. The society believes that the reduction of these accidents lies in the control of the manufacture of fireworks and in education of the public. About 250,000 publications were distributed at the request of 1,419 local communities in the United States and of forty-three foreign communities. There were about 420 showings of the society's film "Preventing Blindness and Saving Sight" reaching an audience of 29,532. Staff members participated in local sight conservation activities in eighty-six cities in twenty-one states. The District of Columbia, Canada and Europe. During the year a study of blindness among 2,700 children in schools for the blind was undertaken by a committee on statistics, which the society and other organizations are sponsoring. The results are expected to determine more clearly along what lines prevention must proceed. It collaborated in the formulation of a national code on safety glass and cooperated with various local agencies interested in legislation requiring the use of safety glass in motor vehicles. It also sponsored the special training of several young women for duty in the social service departments of eye hospitals and eye clinics in Chicago, Pittsburgh and New Orleans. In 1934 the society's income was \$96,900 and its expenditure \$131,900, necessitating the use of \$35,000 from its reserve fund.

Medical Bills in Congress—*Changes in Status*. S J Res 169 has passed the Senate, authorizing Drs Hugh S Cumming, Surgeon General of the United States Public Health Service, John D Long, Medical Director, United States Public Health Service, Bohvar J Lloyd, Medical Director, United States Public Health Service, and Clifford R. Eskey, surgeon, United States Public Health Service, to accept and wear certain decorations bestowed on them by the governments of Ecuador, Chile, Peru and Cuba. S 3060 has passed the House, proposing among other things to extend the provisions of existing law providing hospitalization and domiciliary care for veterans so as to include men discharged from the Army, Navy, Marine Corps or Coast Guard who are in receipt of pension for service connected disability. H R 9116 has passed the House and Senate extending the provisions of veterans laws and regulations to persons who served in Russia during the World War. H R 9185 the Liquor Tax Administration Act has passed the House. It provides among other things, that alcohol may be obtained tax free for the use of any clinic operated for charity and not for profit including use in the compounding of bona fide medicines for treatment outside of such clinics of patients thereof but not for sale. *Bills Introduced*. H R 9145 introduced by Representative Lundeen, Minnesota proposes to provide for the refunding of all benefits to Spanish-American War veterans and their widows and dependents of which they were deprived by the Economy Act. H R 9218, introduced by Representative Kramer, California, proposes to provide that certain service-connected disabilities shall be deemed to have been incurred in World War service.

FOREIGN

Society News—There will be an International Congress for the Scientific Investigation of Population Problems in Berlin, August 26-September 1.—The International Association for Preventive Pediatrics (the medical section of the Save the Children International Union) will meet in Basle, Switzerland, September 20-21. Headquarters of the association are at 15, rue Levrier, Geneva.—Physicians in Tientsin, China, recently organized the Tientsin Medical Society, with Dr Joseph A Mendelson as president. Physicians visiting Tientsin are invited to attend the meetings, which are held the last Thursday in each month.

Conference on Tuberculosis—At a meeting of the executive committee and the council of the International Union Against Tuberculosis in Paris July 10-11, plans were made for the conference to be held in Lisbon, Portugal, September 8-10, 1936. The following subjects will be treated: "Radiologic Aspects of the Pulmonary Hilus and Their Interpretation," with the opening report by Prof Lopo de Carvalho, Brazil, "Primary Tuberculous Infection in the Adolescent and the Adult," by Dr Olaf Scheel, Norway, "The Open Case of Tuberculosis in Relation to Family and Domestic Associates," by Sir Henry Gauvain, London. At the scientific session Professor Thorvald Madsen, Copenhagen, reported on "Tuberculin Standardization and Tuberculin Tests," and Dr Kendall Emerson, New York, on the work of American investigators of tuberculosis.

Government Services

Dr Dunham Named Director of Division of Maternal Health

Dr Ethel C. Dunham, acting director of the division of maternal and child health, U S Children's Bureau, has been named director of the division, succeeding Dr Martha M Eliot, who was appointed assistant chief of the bureau last December. Dr Dunham has been associate clinical professor of pediatrics at Yale University School of Medicine, New Haven, Conn, and has recently been designated lecturer in pediatrics at the school (THE JOURNAL, March 23, p 1017). She graduated from Johns Hopkins University School of Medicine in 1918.

General Patterson Retires and Accepts Deanship

Major Gen Robert U Patterson, formerly surgeon general of the U S Army, will retire from the army, September 1, to become dean of the University of Oklahoma School of Medicine and superintendent of its hospital. Dr Patterson applied for retirement on his return from Brussels, Belgium, where he represented the state department and the secretary of war at the International Medical Congress of Surgeons and Physicians. Born in Montreal, Canada, in 1877, Dr Patterson graduated from McGill University in 1898 and from the Army Medical School in 1902. For his services abroad, General Patterson received the Distinguished Service Medal, also citations for "gallantry in action."

Dr Hasseltine Ill with Psittacosis for Second Time

Dr Hermon E. Hasseltine, U S Public Health Service, is ill in San Francisco with psittacosis. This is the second time that Dr Hasseltine has had the disease. The first attack having occurred in 1930 in Washington, where he was making laboratory studies of the epidemic that then prevailed. For three years Dr Hasseltine was in charge of the psittacosis laboratory of the public health service at Pasadena, which was closed several months ago. He was then detailed to San Francisco to make a study of bubonic plague. While he has not been in contact with parrots recently, it is believed he acquired the infection in Pasadena July 10, from instruments used in previous studies, which he handled while packing them for shipment. He became ill July 25 and on July 28 was admitted to the marine hospital. He is now much improved. So far as the public health service is informed, this is the only instance of psittacosis occurring a second time of which there is record. In March 1930 Dr Hasseltine suffered a moderately severe infection with psittacosis apparently acquired at the National Institute of Health, although definite history of his contact with infected birds could not be traced. His illness occurred at the time that ten other persons connected with the institution were infected. Two of this group were in direct contact with infected birds, but the means of transmission of the disease was not determined in the other cases. Dr Hasseltine has been with the public health service for twenty-six years.

Alcohol and Road Accidents

The question of alcohol and road accidents has received much attention recently. At a meeting of the National Temperance League Mr. Ransom Pickard, president of the ophthalmologic section of the Royal Society of Medicine, pointed out that alcohol diminishes the vision of the peripheral retina before it affects central vision, the opposite to the rule that functions latest developed suffer first. The result is that moving objects are not so well discerned. The Carnegie Institution found that the taking of a little dilute alcohol affected the central vision less than 2 per cent while it affected the peripheral vision up to 11 per cent. Moreover, alcohol prolongs the reaction time, particularly in a street where a bewildering choice of possibilities occur. A pint and a half of ale prolongs a simple reaction time by 97 per cent. Moreover, alcohol increases the sense of satisfaction at impaired performances and engenders a false security, sometimes even bravado, so that driving may be undertaken when dangerous. If a driver who took alcohol were conscious of his defects and took care and drove slowly little harm might result but this he cannot do. The same criticism applies to the pedestrian for one who crosses the road with impaired neuromuscular equipment and similar cocksureness is likely to contribute to the casualty list.
